A final reason for adopting a 'habitat' rather than a 'species' approach to the conservation of tropical biodiversity anticipates the next Section. It is the associated non-biodiversity benefits from habitat preservation, such as watershed protection, harvesting of non-timber forest products and attraction of recreational and scientific tourism (Panayotou and Ashton 1992). These are joint products of habitat conservation but not of species conservation *per se* except for the latter to some degree. In this sense, biodiversity conservation may be thought of as a joint production function with joint inputs and joint outputs. These joint products are of particular importance as a source of livelihood and foreign exchange to developing countries and hence a more compelling reason for conserving biodiversity than the protection of individual species. While the latter is a primary object of biodiversity conservation from the standpoint of developed countries, it is only a by-product from the standpoint of developing countries; it is an added benefit to the host country only to the extent that the ensuing global benefits can be captured through tourism, royalties or international transfers (Panayotou 1992). Carbon sequestration is an additional global by-product of habitat preservation for the purpose of protecting biodiversity that may or may not be internalized to the developing country that hosts tropical forests. However, the adoption of a habitat approach to species conservation does internalize a significant portion of the benefits to the host country through watershed protection, sustainable production of non-timber forest products and enhanced opportunities for local and international tourism. Consideration of these additional benefits has three implications: (a) the conservation of a larger area maybe justified, (b) a somewhat different mix of conservation areas may be chosen to include critical watersheds, tourist attractions, etc. thereby reducing the opportunity costs of conservation, and (c) the motivation of the host country to set aside and protect habitats is thereby enhanced.

For a combination of ecological and economic reasons, therefore, biodiversity conservation in the tropics is a matter of identifying and protecting critical habitats.

However, setting aside land as protected habitat for the conservation of biodiversity and other associated benefits has significant opportunity costs in terms of forgone benefits from alternative land uses. Hence it is necessary to value both the benefits from habitat conservation and the opportunity cost to determine the demand and supply price of biodiversity and the optimum level of biodiversity conservation.

12.2.5 Use value: habitats versus ecosystems

The conservation of individual species implies the conservation of their habitats. But the value of ecosystems extends well beyond their role as habitat for particular species. In what follows we consider how the biodiversity in an ecosystem is related to the provision of the full range of ecological services for which that system may be valued. Since biodiversity, like habitat, is a public good, it is notoriously difficult to obtain reliable statements of willingness to pay for its conservation. This shows up in the value estimates reported later in this section. However, we can leave this problem to one side for now, focusing on the source of the derived value of the mix of species in the provision of ecosystem services.

Our starting point here is the idea that the use value of the composition of species lies in its role in maintaining the flow of services obtained from an ecosystem over a range of environmental conditions. This requires the specification of an appropriate 'production function' describing the relationship between inputs and outputs (Smith 1991; Perrings *et al.* 1993). Specifically, it requires that the individual species in an ecosystem are conceptualized as inputs to the production of useful goods and services. Their value, like the value of other inputs, derives from the value of the goods and services they support. If an output depends on the contribution of a different set of organisms under one possible state of nature than it does under another, and if the output has value under both states of nature, then both sets of organisms will have derived value. The use of this approach requires an analysis that is as much ecological as it is economic. The ecological analysis is needed to identify the role diversity plays in maintaining the structure and function of ecosystems. The economic analysis is needed to derive the value to individuals and societies of the function of ecosystems in the production of goods and services from this information. Both analyses are necessary.

One of the major 'risks' associated with the loss of biodiversity is that present ecosystems and ecosystem processes might be transformed into new configurations with unknown consequences for human welfare. To the extent that biodiversity supports ecological services in the face of variable environmental conditions it has indirect value: the value of ecological resilience. Note that resilience has a very particular meaning here. It is a measure of the magnitude of disturbance that can be

absorbed before the system changes its structure by changing the variables and processes that control behaviour. Such changes – from forest to grassland, from savannah to shrublands, from grassland to desert, for example – reflect a loss of structural resilience (implying an increase in the vulnerability of the system to variability in environmental conditions and a loss of predictability).

This differs from the traditional concept of resilience in ecology discussed in Sections 5 and 6, though both refer to properties of the stability of a system. Resilience in the traditional sense is a measure of resistance to disturbance and speed of return to the equilibrium state of an ecosystem (Pimm 1984; O'Neill *et al.* 1986). This may be called 'equilibrium resilience'. The term as it is used in the previous paragraph may be termed 'structural resilience'. In contrast to equilibrium resilience, it measures the limits of the stability of a system, and may be defined for any state of that system, however far from equilibrium (Holling 1973). The consequences of those different aspects were first contrasted by Holling (1973) for ecological systems, in order to draw attention to the paradoxes between efficiency and persistence, constancy and change, order and disorder. In ecological systems characterised by hierarchical structures, each with distinct spatial and temporal frequencies, and with different abiotic and biotic processes that control different functional states, structural resilience may be the more relevant concept.

The value of biodiversity from this perspective lies in the role of the composition of species in maintaining the critical processes of terrestrial ecosystems (where most of the threat to biodiversity lies) over a range of states of nature. This reflects the emergence of a consensus among a subset of community and systems ecologists who deal with regional-scale systems and the interactions of processes across scales. This consensus identifies three propositions concerning the structure and dynamics of terrestrial ecosystems: that the diversity and complexity of ecological systems can be traced to a small set of biotic and abiotic processes, each operating over different scale ranges (Holling 1992; Holling *et al.* 1995); that animals and plants can shape their ecosystems (Schindler 1977; McNaughton *et al.* 1988); and that species dynamics (and so biodiversity) tend to be more sensitive to stress than are ecosystem processes (Schindler 1990b; Vitousek 1990). Despite a background of disagreement about the role of ecosystem complexity in ecosystem stability, this has led this subset of community and systems ecologists toward the view that there does exist a reasonably well defined relationship between functional diversity and ecosystem resilience. In supporting ecosystem resilience the functional diversity of species provides a means of minimizing the risks of fluctuating environmental conditions. Biodiversity conservation may therefore be thought of as a means of managing uncertainty, and hence the value of biodiversity includes a significant insurance component.

There is, however, a dynamic interdependency between economy and ecosystem. The properties of biophysical systems are part of the constraints set which bounds economic activity. The constraints set is linked to economic activity which is exploiting environmental assets (extraction, harvesting, waste disposal, non-consumptive uses) and feedbacks then occur which influence economic and social relationships. As the evolution of the economy and the evolution of the constraints set are interdependent, 'co-evolution' is thus a crucial concept (Common and Perrings 1992).

Norton and Ulanowicz (1992) advocate a hierarchical approach to natural systems (which assumes that smaller subsystems change according to a faster dynamic than do larger encompassing systems) as a way of conceptualizing problems of scale in determining biodiversity policy. For them, the goal of sustaining biological diversity over multiple human generations can only be achieved if biodiversity policy is operated at the landscape level. The value of individual species, then, is mainly in their contribution to a larger dynamic and significant financial expenditure may not always be justified to save ecologically marginal species. A central aim of policy should be to protect sufficient 'chunks' of ecosystem necessary to maintain the system's functioning, rather than individual species conservation *per se*.

Ecosystem health (stability and resilience or creativity), interpreted in terms of an intuitive guide, is useful in that it helps focus attention on the larger systems in nature and away from the special interests of individuals and groups (Norton and Ulanowicz 1992). The full range of public and private instrumental and non-instrumental values all depend on protection of the processes that support the health of larger-scale ecological systems. Thus when a wetland, for example, is disturbed or degraded, we need to look at the impacts of the disturbance on the larger level of the landscape. A successful policy will encourage a patchy landscape.

The 'integrity' of an ecosystem is more than its capacity to maintain autonomous functioning (its health): it also relates to the retention of 'total diversity' (Norton 1992), i.e. the species and interrelationships that have survived over time at the landscape level. A number of ecological services and functions can be valued in economic terms, while others cannot because of uncertainty and complexity conditions. Taking wetlands as our example, these systems provide a wide array of functions, services and goods of significant value to society – storm and pollution buffering, flood alleviation, recreation and aesthetic services, etc. We can therefore conceive of 'valuing' a wetland as essentially valuing the characteristics of a system. Since it is the case that the component parts of a system are contingent on the existence and continued proper functioning of the whole, then putting an aggregate value on wetlands and other ecosystems is quite a complicated matter.

Economic values may not capture the full contribution of component species and processes to the aggregate life-support functions provided by ecosystems (Gren *et al.* 1994). Furthermore, some ecologists argue that some of the underlying functions of ecological systems which are basic to the ecological functions cannot be taken into account in terms of economic values. Total Economic Value will therefore underestimate the true value of ecosystems. The prior value of the ecosystem structure has been called 'primary value' and consists of the system characteristics upon which all ecological functions depend. Their value arises in the sense that they produce functions which have value (secondary value). The secondary functions and values depend on the continued 'health', existence, operation and maintenance of the ecosystem as a whole. The primary value notion is related to the fact that the system holds everything together (and is thus also referred to as a 'glue' value) and as such has, in principle, economic value. This is unmeasurable in terms of consumer preferences and so the social value of an ecosystem exceeds the sum of the values of the individual functions (Turner and Pearce 1993). It can also be argued that a healthy ecosystem contains an ecological redundancy capacity and there is thus an 'insurance' value in maintaining the system at some 'critical' size in order to combat stress and shocks over time.

12.2.6 Concluding remarks

To summarize:

- The direct use value of biological resources derives from their direct role in consumption or production. Agriculture, forestry and fisheries are all based on the direct use value of foods and fibres.
- The indirect use value of biological resources stems from the fact that they are necessary to the production of resources which have direct use value.
- The value of the mix of biological resources, biodiversity, is an indirect use value. It derives from the role of the mix of species in (a) supporting one or more organisms (the value of habitat) and (b) supporting the provision of the economically interesting range of ecological services (the value of ecosystem functions).
- The value of ecosystem functions is sometimes referred to as a secondary value, in contrast with primary value – the value of the system characteristics upon which all ecosystem functions depend.
- The non-use or passive use values of biological resources derive from: altruism towards friends, relatives or others who may be users (vicarious use value); altruism towards future generations of users (bequest value); and altruism toward non-human

users (existence value). It may often be framed by the individual either in terms of rights assigned to others or in terms of codes of behaviour.

- The social value of an ecosystem exceeds its private or market value as conventionally calculated because of the following factors:
 1. The full complexity and coverage of the underpinning 'life-support' functions of healthy evolving ecosystems are currently not precisely known in scientific terms. A number of indirect use values within systems therefore remain to be discovered and valued.
 2. Because the range of secondary values (use and non-use) that can be (in the main) instrumentally derived from an ecosystem is contingent on the prior existence of such a healthy and evolving system, there is in a philosophical sense a 'prior value' that could be ascribed to the system itself. Such a value would not, however, be measurable in conventional economic terms and is non-commensurate with the economic (secondary) values of the system.
 3. The continued functioning of a healthy ecosystem is more than the sum of its individual components. There is a sense in which the operating system yields or possesses 'glue' value, i.e. value related to the structure and functioning properties of the system which hold everything together.
 4. A healthy ecosystem also contains a redundancy reserve, a pool of latent keystone species/processes which are required for system maintenance in the face of stress and shock. Both factors 3 and 4 could, in principle, be valued.

Estimation of the total value of wetlands, forests, etc. involves complex problems to do with system boundaries, scale, thresholds and value component aggregation. Given the inevitable uncertainties involved, a precautionary (risk averse) approach based on maximum ecosystem conservation is a high priority. So in this sense the primary value concept (in terms of value dimensions 1, 3 and 4 above) is directly relevant to the conservation versus development policy debate. A 'healthy' ecosystem is seen as being valuable beyond benefits that can be computed simply in terms of consumptive preferences. Self-organizing systems maintain a degree of stable functioning across time. They provide a sufficiently stable context to which human individuals and cultures can adapt their practices. Ethically it could be argued that sustainability could be interpreted as requiring that no

generation has a right to destabilize the self-organizing systems that provide the context for all human activity and therefore possess 'primary' value (Costanza *et al.* 1992).

This does not, however, mean that all environmental assets have unmeasured value and therefore all assets should be protected. Rather it is the on-going 'healthy' system that possesses primary value and this requires biodiversity conservation at the landscape scale. There is still, however, the thorny problem of actually deciding, on a rational basis, the 'scale' from which to manage environmental public goods. The 'scale' choice problem is in fact a public policy decision and as such is underdetermined by the mere provision of scientific information. Available scientific information contains inaccuracies and uncertainties such that it is not possible to specify minimum viable populations and minimum habitat sizes for the survival of species (Hohl and Tisdell 1993). Biodiversity conservation decisions, for a considerable time to come, will have to include ethical considerations. It has been concluded that 'society may choose to adopt the safe minimum standard not because it results from a rigorous model of social choice, but simply because individuals in the society feel that the safe minimum standard is the 'right thing to do'' (Bishop and Ready 1991). But let us not forget the significant use value that biodiversity possesses. A suitable comprehensive and long-term view of use value – one that protects ecosystems' services by protecting the health and integrity of systems over the long term – is probably sufficient to realize the case for more biodiversity conservation and will carry with it aesthetic and intrinsic moral values as well (Turner 1988a; Costanza *et al.* 1992). Adoption of the safe minimum standard and the precautionary principle also shifts the burden of justification to those who would destroy biodiversity because of their development activities.

12.3 The valuation of biodiversity: theory and methodology

12.3.1 Introduction

It is clear from the foregoing discussion of the components of the demand for biodiversity that its valuation is far from trivial. This is partly due to the very well recognized problems of the non-existence of well-functioning markets for many biological resources, and the public good nature of biodiversity. Both things imply that there is no ready index of value. Both also imply that the social value of biological resources cannot in general be derived from a simple aggregation of their value to individuals in society, the sum of their private values. Moreover, if individuals have distinct preferences as consumers and citizens, estimation of the social value of biological resources with at least some of the attributes of a public good is doubly problematic.

Where decision-making households or firms are so small that no single agent can influence price, and where markets are well-functioning, each actor responds quantitatively to exogenous price changes and it is possible to use market observations to characterize their behaviour in response to price changes and other exogenous influences. However, we are rarely able to obtain behavioural observations directly from markets for environmental resources because these markets typically do not exist. Economists therefore pursue one of two alternative strategies. The first, referred to as stated preference methods, avoids conventional markets and searches simulated markets. By this is meant that a survey instrument is designed in which a market-like situation is constructed. Respondents record choices in the light of hypothetically changed circumstances and the data are used to value environmental amenities and other goods or services. This avenue of attack has various generic names. The fact that there is no settled title reflects its youthful origins. It is sometimes called 'direct' or stated preference, because the analyst circumvents the market and goes directly to the wellspring of taste formation. At other times the distinction is made between a 'simulated' and a real market. 'Constructed market' is a more recent arrival.

The second strategy is to infer values from data on behavioural changes in actual markets related in some way to the missing markets for environmental resources. Travel cost, hedonic valuation and production function approaches are examples. Illustratively, through econometric analysis, the analyst separates the money value of an environmental amenity from the market price of residential property, of which air quality, for example, is but one characteristic. Alternatively, although there may be no market value for a wilderness area its value can be derived by analysing the demand for trips to the area, by those who face different costs per trip. Again, the value of the wilderness is separated from the value of the composite commodity, a trip. More generally, the value of an environmental amenity is 'indirectly' obtained from or 'revealed' by the demand for a related good/service.

Biological resources are a critical constituent in many marketed goods. In these cases such resources have direct or indirect use value. But the point has been made in earlier chapters that people also value natural resources irrespective of their own use of them. Some people have strong positive feelings about the existence of wild game in Africa and elsewhere. They are deeply concerned that the existence of rhinoceros and other species is threatened, so much so that they willingly contribute money toward preservation of these species. Some know that they will never themselves see those species in the wild but nonetheless contribute money to increase the chance that they will be available for future generations to enjoy. Existence and bequest values are strong motivating forces for understanding non-use values.

Figure 12.3-1: Environmental Commodities Spectrum and the Valuation Problem.

In both approaches the problem of valuation is exacerbated by the public good nature of biodiversity. In economic terms pure public goods differ from private goods because they are non-rival in consumption terms (i.e. consumption of the good by one individual does not preclude consumption by others) and non-exclusive (i.e. having provided the good it is impossible, or excessively costly, to operate any exclusion mechanism). In practice there are very few pure public goods but many environmental goods and services fall between the polar public and private good cases. Thus so-called international common pool resources (e.g. fisheries and migratory species such as wildfowl and whales) have in the past been non-exclusive, open-access resources which have appeared to be also non-rival. Excessive exploitation and consequent depletion has resulted because of open access and the fear that exploitation would eventually become 'congested'; and most of this type of resources has now become a rival/contestable good. International management of these resources including regulation of exploitation is generally necessary to prevent open access depletion.

It turns out that the public good nature of biodiversity creates a particularly intractable set of problems for its valuation. These are discussed in the context of particular examples below, but they may be illustrated schematically. Figure 12.3-1 relates the difficulty of valuing environmental resources to the public good nature of those resources.

12.3.2 Stated preference methods: contingent valuation and contingent ranking

12.3.2.1 Contingent valuation

Contingent valuation and contingent ranking are two major techniques developed by social scientists for estimating non-market values. Contingent ranking is discussed momentarily. Put briefly, the contingent valuation method (CVM) involves asking respondents hypothetical questions about their monetary valuation of a situation, here involving a biodiversity issue. For example, (Whitehead 1993):

Suppose that a [US\$10] contribution...would be needed to support and fund the loggerhead sea turtle program. Would you be willing to contribute [US\$10] each year to the 'Loggerhead Sea Turtle Preservation Trust Fund'...?

There is, of course, more to the CVM than this. It involves conducting a survey by mail, telephone or personal interview which has three essential components.

First, background information about the natural resource setting and circumstances is provided. The respondent is advised about the quantity, quality and duration of change in the natural resources.

Second, a payment instrument is chosen. In the example above, the respondents were asked to contribute to a hypothetical fund. In the *Exxon Valdez* oil spill case, respondents were asked to vote for a referendum resulting in a tax increase in the study done for the State of Alaska

(Carson *et al.* 1992). In other surveys, the payment vehicle is an increase in product price. For example, harvest restrictions to preserve wild salmonid species in the Pacific Northwest could increase retail salmon prices. Throughout the process, focus groups and other means are used to understand what is and isn't being understood. The background information and payment vehicle are not independent elements. The researcher must take great care in characterizing a plausible and acceptable scenario. Illustratively, respondents will refuse to respond, or respond inappropriately, if they hate taxes and the vehicle is a tax change; if they don't believe a cost incident on producers will be passed on to them; if they think a special purpose public building fund for a limited duration will be used for purposes other than improving biodiversity, will be extended longer than was stated or will be spent wastefully – liberties they may have observed public authorities to have committed in similar situations in the past. The challenge is to devise a credible instrument.

Third, a method of elicitation is chosen. One approach, called open-ended, asks the respondent to state a maximum amount he/she is willing to pay (or to receive). A second approach, illustrated above in the case of turtles, is called dichotomous choice, in which a respondent is asked whether, for example, he/she would pay X dollars for the environmental change (or no change) in question. The amount, X , is systematically varied across the sample population. Other approaches exist (Carson *et al.* 1995).

More than 2000 studies using the CVM (Carson *et al.* 1995) have been conducted throughout the world and the number is growing rapidly. However, comparatively few relate to biodiversity (Portney 1994; Hanemann 1994; Diamond and Hausman 1994). Research bearing on endangered or unique species, in addition to the study of loggerhead sea turtles (Whitehead 1993), includes the value of preserving the whooping crane population at the Arkansas National Wildlife Refuge in Texas for viewers and non-viewers, estimated by Stoll and Johnson (1984) and Bowker and Stoll (1988). Hagemann (1985) valued blue whales, bottlenose dolphins, California sea otters and northern elephant seals. Brown and Henry (1993) estimated the value of preserving elephants in Kenya. Boyle and Bishop (1987) estimated the value of preserving the striped shiner, a Wisconsin endangered species. Boyle and Bishop (1986) also have estimated the existence value for eagles (also an endangered species in Wisconsin) focusing, in part, on whether respondents view eagles or not. The last three studies vary in detail and in the exact concept of existence value measured but they closely resemble each other in such important considerations as survey delivery (mail questionnaire); payment vehicle (contribution to a fund/foundation); and type of question (dichotomous choice and open-ended). In addition, Spash and Hanley (1995) and Hanley *et al.* (1995) have evaluated the

problem of information in the valuation of biodiversity. The results of some of these surveys are reported in Chapter 12.5.

Hagen *et al.* (1991) and Rubin *et al.* (1991) differ from the three studies above. The first set of authors estimated the value of preserving the Northern spotted owl using a tax and price increase scenario and the latter study used a payment card format with a matrix of annual values to elicit an open-ended maximum willingness to pay value for the Northern spotted owl. The estimated values varied by more than a factor of five between these studies for reasons difficult to characterize precisely because the study designs exhibited great variations in details.

12.3.2.2 Contingent ranking

The contingent ranking method is a step-sister to the contingent valuation method; relatively few have been carried out. The distinctive ingredient in a contingent ranking study is a menu of alternatives. The respondent is asked to rank one or more, up to all, of the options in order of preference. The researcher identifies a set of important attributes or characteristics common to each item on the menu and the amount by which one or more of the attributes differ for each option on the menu. For example, in order to value different endangered species, a researcher might think that taxonomic distinctiveness is important, such as monotypic or subspecies, taxonomic class such as mammal, bird, other, and some measure of size such as mass or length to capture 'charismatic megafauna'. For economic valuation, a money metric is necessary. This is achieved, say, by introducing the cost of a preservation programme. Thus both cost and one or more levels of preservation would have to be specified for each item on the menu. Basically the respondent is comparing added money cost with added pay-off measured in additional physical characteristics. The respondent ranks highest that option which provides the 'biggest bang for a buck'. Clever survey design aided by competent econometric analysis allows the researcher to conclude which menu, policy choice, species, etc. is the most valued, second most valued, etc. One can also estimate the value of a marginal improvement in chance of survival, population size, and other characteristics such as habitat complexity, if 'complexity' can be described in a manner which respondents can order.

A feeling for the level of complexity that can be encompassed by contingent ranking methods is illustrated by an early and ambitious model outside the realm of biodiversity. Beggs *et al.* (1981) valued the characteristics of automobiles, with particular emphasis on electric power. There were 16 items on the menu, each of which had nine attributes. Respondents were asked to rank the various options!

There are not enough data to compare the contingent valuation method with the contingent ranking method, but

two observations seem reasonable. First, it would seem to be easier to order two alternatives in the contingent ranking situation compared to choosing whether an option or policy is worth at least a given money value. As the number of required ordinal rankings increases, the advantage of contingent ranking over contingent valuation decreases. Second, non-market valuation studies continuously have to defend in design and concept against the phenomenon variously called part-whole bias, warm glow or embedding. If one is asked to value biodiversity or an improvement in the state of biodiversity, the respondent may have a mental model that fails to distinguish between this specific element and the value of a more encompassing concept such as environmental improvement or altruism. If a respondent has a propensity to embed or to have a warm glow, then it is easier for him/her to agree to pay a specified amount for a given environmental improvement than not. Put differently, one might expect the response to a maximum willingness to pay question to have a monetary value which includes an embedding component in it. Matters are different in the contingent ranking approach because it is marginal in nature. If one is an embedder or has a warm glow, this should exist for every option. Contingent ranking is designed to elicit the marginal change in valuation, i.e. the difference between two options. In this case, all or most of the embedding present should fall out when, in effect, the value of one option is subtracted from another.

Contingent valuation and ranking techniques, or more euphemistically, values estimated from simulated markets are very controversial within the economics profession. It is predisposed to favour market observations. Kenneth Arrow captured the issue nicely when he said that '[V]erbal answers don't hurt the way cash payments do' (in Cummings *et al.* 1986). Some have argued that values obtained from the CVM should play no role in policy analysis (Hausman 1993). Critical evaluation has been heightened, now that the technique has been legally authorized in the United States for use in natural resource damage assessment. Controversy about its applicability in the *Exxon Valdez* damage assessment legal proceedings led to the formation of the NOAA panel on contingent valuation which comprised two Nobel prize winners in economics and others (Arrow *et al.* 1993). Their report lays down criteria that a proper study using the CVM should meet in the context of a legal suit involving enormous sums of money. To satisfy their standards, a survey would cost millions of dollars. Adherents to their criteria would reject data from the US Census because a mail survey is used. Readers interested in the issue can review the litany of biases it is important to avoid (Cummings *et al.* 1986; Mitchell and Carson 1988; Hausman 1993). The extraordinary intellectual ferment that has been generated is exciting and reflects what should be expected when a promising research method is in early stages of

development. One cannot simply stand aside for years until the issues are settled, unless one is prepared to leave non-use values unmeasured. An alternative is to fashion an interdisciplinary research design, including critics in the process. Even then, the task is not easy. Here are two illustrative issues. What is the optimal amount of information to provide, keeping in mind that people who purchase market goods have a distribution of information about these goods? Responses vary with the level of information provided (Irwin *et al.* 1992; McClelland and Schulze 1993).

What elicitation method is best? It has been argued that it is harder and takes more information, to respond to an open-ended, maximum willingness to pay question, than it takes to answer a dichotomous choice question, so the latter approach is now more popular. Statistically, it is not very efficient to know that one values viewing elephants either more or less than US\$100. In response, a technique known as double bounded dichotomous choice has been developed. If a respondent says yes to the first value, he/she is asked to respond to a higher specified value and if the response is no, then a lower value is offered. This technique is popular. Responses to an open-ended design are virtually always lower by several multiples, when the goods are non-market (Schulze *et al.* 1994). Moreover, the double bounded approach has brought further difficulties. Analytically, responses to the first question should have the same distribution as responses to the second question. Thus far, this has not been the case (McFadden and Leonard 1993; Brown *et al.* 1994; Cameron and Quiggin 1994; Alberini 1994). In fact, the mean of the second response tends to be smaller. Why? Maybe it is because of an old problem in new clothing, starting point bias, where the number a respondent first sees influences the response. In any event, it is much too soon to know whether a design innovation can remove the problem. New evidence from experimental economics criticizes the double bounded approach on the grounds that, in experimental designs, it gives an overestimate of market values, more closely approximated by responses to an open-ended design question (Schulze *et al.* 1994). However, estimates of value from open-ended questions tend to overestimate but to a lesser degree than the close-ended question format.

Finally, rarely is policy-making a binary choice. Usually, debate in public forums encompasses a variety of options in which a bit more improvement in biodiversity can be obtained for a bit more expenditure. Not many CVM studies exhibit this design feature. To this end, it behoves researchers to design studies that inform them about how economic value varies with scale of effort. It is likely that the public places a different value on reducing the probability of extinction by ten points, from 30 to 40% chance of survival than they place on improving survivability from 80 to 90%. Thus a successful and

well-designed study provides a total benefit function which captures how total benefits vary as one or more measures of biodiversity captures are changed

According to some analysts, the economic literature which seeks appropriately to define and measure existence value as part of a comprehensive valuation framework has arrived at a consensus view that both use value and non-use value can be distinguished formally using standard welfare measures from neoclassical economic theory (Larson 1993). Other analysts highlight the differences that have emerged in the literature (Lant 1994). A number of writers also seem to agree that existence value can only be measured by survey methods (contingent valuation methods). Since existence values involve neither personal consumption of derived products nor *in situ* contact, economists have used a special structure of preferences to model existence value. They have assumed either so-called 'weak separability' or 'strong separability' between the non-market good that is the subject of existence value motivated by individuals and market goods. When preferences take these forms, the non-market good cannot be identified via conventional market demand theory and analysis. Existence value of the non-market good cannot therefore be measured by indirect observation of the individual's behaviour and the only option is direct questioning via surveys.

Larson (1993) has questioned some of this consensus thinking and in particular argues that in a number of real world choice situations neither 'weak' nor 'strong' separability assumptions are very realistic. Instead it is likely in a number of situations that changes in the level of the public good will give rise to existence value that is traceable in principle from observed changes in behaviour (spending money and/or time in reading about or protesting in some way about the environmental change, e.g. species or habitat loss or degradation). It remains to be seen whether valuation techniques other than contingent valuation (or proxy measures such as debt-for-nature swap expenditures) can adequately capture aspects of existence value. Some economists and many non-economists also question whether in practice contingent valuation methods can yield reliable measures of existence value. The methods are both expensive and demanding on researchers if acceptable reliability and validity testing protocols are to be met.

12.3.3 Revealed preference methods: travel cost and random utility models

We now consider the indirect or revealed preference methods for eliciting the private value of environmental resources. Direct methods involve direct measurements of utility, using some form of stated preference approach. In contrast, indirect methods seek to recover estimates of individuals' willingness to pay (WTP) for environmental

quality by observing their behaviour in related markets. In the hedonic pricing example already referred to, the related market for urban air quality is the housing market, and economists seek to infer individuals' valuation of air quality improvements by considering their behaviour in this market. In the travel cost model, the analyst infers the value people place on an outdoor recreational site through their expenditure on travel to the site. The random utility model also makes use of travel expenditures. Both travel cost and random utility models can be used to estimate the value of individual species, but their usefulness in valuing biodiversity itself may be viewed as being rather limited. Hedonic pricing methods would seem to offer very little scope for the valuation of biodiversity, so are not included in this section: see Hanley and Spash (1994) for a description of these methods. Dose-response and production function models (described elsewhere in this chapter) are also usually categorised as indirect valuation methods.

12.3.3.1 The travel cost model

The travel cost model (TCM) is one of the oldest approaches to environmental valuation, first used by Wood and Trice in 1958, and popularized by Clawson and Knetsch (1966). The method involves using travel costs as a proxy for the price of visiting outdoor recreational sites. A statistical relationship between observed visits and the cost of visiting is derived, and used to derive a surrogate demand curve from which consumers' surplus per visit-day can be measured (by integrating under this curve). The method has been widely used in both the USA and the UK for valuing the non-market benefits of outdoor recreation, especially recreation associated with national parks and public forests (Bowes and Krutilla 1989). Recent developments of the technique allow the welfare effects of changing the characteristics of a site to be analysed. An excellent recent survey of the method may be found in Fletcher *et al.* (1990).

The travel cost method assumes *weak complementarity* between the environmental asset and consumption expenditure. This implies that when consumption expenditure is zero, the marginal utility of the public good is also zero. So if travelling to a forest becomes so expensive that no one goes any more, the marginal social cost of a decrease in the quality of that forest is also zero. The TCM cannot therefore estimate non-use values (although see Larson (1992) for a contrary argument). As has already been remarked in this section, an implicit assumption also made in most travel cost studies is that the representative visitor's utility function is 'separable' in the recreation activity being modelled. This means that, if the activity of interest is fishing, then the utility function is such that demand for fishing trips can be estimated independently of demand, say, for cinema trips (alternative leisure activities) or for heating oil (alternative marketed

non-leisure goods). Finally, like all other valuation methods, the TCM assumes the existence of utility functions where the environment appears in a similar manner to other goods. In particular, the assumption is made that individuals are willing to trade off changes in environmental quality against changes in other goods or income. For a contrary view, see Sagoff (1988), Blamey and Common (1994) and Spash and Hanley (1995).

The simplest version of the travel cost model involves collecting data on visits to a site (V) from different parts of the surrounding country (zones, i), and explaining the visit rate per capita (V_i / P_i) as a function of travel costs, C_i . These costs are assumed to be some function of both distance and time spent travelling (travelling time is often allocated a positive value to reflect the scarcity of leisure time); and of socio-economic variables S_i :

$$V_i / P_i = F (C_i, S_i) \tag{1}$$

By predicting how visits per capita will fall as travel costs rise, a demand curve can be traced out for each zone, up to the cost at which visits become equal to zero (although in some functional forms of equation (1), visits will only approach zero asymptotically). Alternatively, visits per time period by a given individual j to a site (VPA_j) may be used as the dependent variable, with the C and S terms becoming specific to that individual.

Many problems exist with such a simple model of the benefits of a single site. Most notably, the effects of other substitute sites are not included (Hof and King 1982). This could be corrected by estimating, instead of equation (1):

$$V_i / P_i = F (C_i, S_i, X_i) \tag{2}$$

where X_i is a vector of 'prices' (that is, visiting costs) for other, substitute sites (Caulkins *et al.* 1986). Alternatively, equation (2) may be estimated simultaneously for a group of sites (for example, all public forests within a region) (Burt and Brewer 1974). Again, VPA may be the dependent variable rather than V/P .

Several problems exist with the model. These include, first, the value of travel/leisure time. Some authors (Chevas *et al.* 1989) have argued that a distinction should be made between the 'commodity value' of time (time spent on-site that generates utility); and the opportunity cost of time, which may be in terms of forgone earnings (in a minority of cases) or forgone recreational opportunities. Chevas *et al.* find the commodity value of time to be positive but small, and call for this to be netted out from the opportunity cost of time in calculating consumers' surplus. The choice of a value for the cost of travel time can cause significant changes in consumers' surplus estimates. Such changes can also be caused by the choice of dependent variable (V/P or VPA). Garrod and Willis (1991) obtain estimates of

consumers' surplus per visit day for UK forests which range from £1.44 to £2.60 for V/P , and £0.12 to £0.96 for VPA. In informal recreation settings recall errors may be a problem in VPA data. Changes in consumers' surplus can also be brought about by the selection of functional form for the visit-travel cost equation. Hanley (1989) reports a variation from £0.32 per visit (quadratic), £0.56 (semi-log independent), £1.70 (semi-log dependent) and £15.13 (log-log) for visits to Achray Forest in Central Scotland.

Another problem with the simple travel cost model considered here is that of multi-purpose trips. It may be necessary to distinguish 'meanderers' from 'purposeful visitors' in the sample of visitors to a site. The former describes those for whom a visit to the site in question is only part of the purpose for their journey. The latter term describes those for whom a visit to the site is the sole purpose of their trip. Consider people visiting a lake in a national park, who are also going on to visit a forest in the same national park. Clearly, some of the travel cost for such meanderers should be excluded from the minimum value they place on a visit to the lake, because they are also going to visit the forest during the same trip. Some of their travel costs should be apportioned to the lake, but how much? There are three options. The first is to ask people to score the relative importance of a visit to the lake; that is, relative to their enjoyment of the entire trip. This score, expressed as a number between 0 and 1, can be used to weight their total travel cost (e.g. Hanley and Ruffell 1993). Second, meanderers may be excluded from the TCM analysis and a per visit consumers' surplus figure, based on these functions, computed. This average visitor consumers' surplus can then be aggregated across all visitors. This assumes, however, that meanderers, on average, value the site no less highly than purposeful visitors. Finally, separate demand functions could be estimated for each group.

Finally, Randall (1994) has made a somewhat more fundamental criticism of the TCM. This is that the researcher's measure of costs may be very different from the cost perceived by the recreationalist. It is this perceived cost (which is largely subjective) that influences the decision on whether or not to visit a site. Yet the researcher cannot measure this perceived cost. It may well differ from the researcher's estimate of it (if, for example, the researcher's estimate of the value of leisure time differs from the value perceived by the recreationalist). Thus the researcher may make incorrect inferences about the revealed value of the recreation site.

On many occasions, policy-makers are more interested in the value of changing the characteristics of a site rather than the value of the site in total. The travel cost model can be used for such calculations. A good example relates to changes in fishing quality at freshwater fishing sites. Two approaches may be distinguished: first, a 'varying

parameter' model, whereby travel cost equations are initially estimated across a group of fishing sites. The travel cost coefficients from these equations are then regressed on the site characteristics (such as water quality, catch rates) across the sites in the sample.¹ This enables the welfare gain associated with changing one of these characteristics to be estimated (Vaughn and Russell 1982; Smith *et al.* 1983). In the second approach, characteristics are used as shift variables in the visits–travel cost relationship. This was the approach taken by Loomis *et al.* (1986) to measure recreational fishing losses due to hydroelectric developments.

12.3.3.2 The hedonic travel cost model

The Hedonic Travel Cost Model (HTC) also attempts to place values on the characteristics of recreational resources. It was first proposed by Brown and Mendelsohn (1984), and has been applied to forest characteristics by Englin and Mendelsohn (1991) and to coastal water quality by Bockstael *et al.* (1987). The method is implemented as follows. First, respondents to a number of sites (e.g. forests) are sampled to determine their zone of origin. Levels of physical characteristics (such as broadleaved/conifer areas and the percentage of forest as open space) are recorded for each site. Next a travel cost function is estimated for each zone:

$$C(Z) = c_0 + c_1z_1 + c_2z_2 + \dots + c_mz_m \quad (3)$$

where $C(Z)$ are travel costs, z_1 is distance to site, $z_2 \dots z_m$ are characteristics, and $c_0 \dots c_m$ are coefficients to be estimated. A separate regression is performed for each zone of origin, so that each will have a vector of coefficients $\{c_0 \dots c_m\}$ associated with it. For a given characteristic m , the utility maximizing individual will choose visits such that the marginal cost of the characteristic (the coefficient c_m) is just equal to the marginal benefit to him/her. These marginal costs will vary, for a given characteristic, across zones of origin. As the forest (for example) is assumed to be a public good (and thus consumption of its recreational opportunities is non-rival), the marginal social value is the sum of all individual (zonal) marginal values. In Englin and Mendelsohn (1991), some of these marginal values are negative, implying that the individual would drive further to have less of the good. This is explained by Englin and Mendelsohn as being related to either undesirable characteristics (such as clear-cut), or cases where the individual is over-satiated with a desirable characteristic. In Bockstael *et al.*, most of the marginal values which were thought *a priori* to be positive turned out to be negative in the estimation.

The second stage of the Brown–Mendelsohn approach is to estimate a demand curve for each characteristic. This is done by regressing site characteristic levels (the dependent variable) against the predicted marginal cost of that characteristic (which is implicitly the marginal value as explained above), and socioeconomic variables for each zone of origin. A separate regression is run for each characteristic. The expectation is that the coefficient on the marginal cost variable will be negative, so that as the level of a characteristic rises, people are unwilling to pay as much for each further increment. Englin and Mendelsohn find this to be so for ten out of eleven characteristics modelled.

However, the HTC method has dropped somewhat out of favour with environmental economists due to a number of problems, highlighted in papers by Bockstael *et al.* (1981) and Smith and Kaoru (1987). First, the marginal value of a characteristic in the HTC method is given by the extra costs individuals are prepared to spend to enjoy, for example, a river with a higher amenity value than a less-visited, lower amenity site closer to home. Yet these relative values (that the clean river costs more to visit than the dirty river) are an accident of nature, in that the clean river just happens to be further away. Bockstael *et al.* give the example of the valuation of two characteristics of lakes, namely scenic beauty and fish catch. If fish catch increases with distance from a major population centre but scenic beauty simultaneously declines, then a positive price (value) for scenic beauty will not be found. Many authors have in fact found negative prices for characteristics which would be expected to have positive marginal values (see above). These difficulties have led some researchers to seek an alternative method of valuing site characteristics, with current research interest being centred on the random utility model of recreational demand.

12.3.3.3 The random utility model

The random utility model of recreational demand (Bockstael *et al.* 1987; Coyne and Adamowicz 1992; Adamowicz *et al.* 1994) shares a theoretical foundation with some stated preference approaches, in particular the dichotomous choice variant of CVM. This is that utility is assumed to be composed of an observable, deterministic component and a random error term. Travel cost and characteristics data are collected for a number of substitute sites in an area. The probability that a given individual will visit site i rather than site j can then be calculated, dependent on the costs of visiting each site and their characteristics, relative to the characteristics of all sites in the individual's choice set. In turn, estimates of the welfare effects of changing a characteristic can be arrived at. Bockstael *et al.* estimate a random utility model for choice of saltwater beach sites in the Boston area, and show that sites with higher pollution levels, higher noise levels, and

¹ These two steps can, in fact, be combined by specifying interaction terms between characteristics and travel costs in the initial equation: see Hanley and Ruffell (1993).

more crowding are less likely to be chosen. They also estimate a 'count' model which predicts how many trips will be made in total to all beaches in the area. Combining these models they are able to calculate the money value of benefits associated with reducing oil, chemical oxygen and faecal coliform pollution levels at all sites in the study area.

The reliability and validity of travel cost models have been addressed in a number of ways, including the use of the 'convergent validity' criterion, whereby travel cost estimates for one site are compared with contingent valuation estimates for the same site (e.g. Sellar *et al.* 1985; Smith and Desvouses 1986). Another interesting approach has been the use of meta-analysis. This involves trying to explain statistically the variation in consumers' surplus per visit across a large number of travel cost studies, according to the manner in which each was carried out. Smith and Kaoru (1990) were able to explain 43% of the variation in consumers' surplus figures across a sample of TCM studies, and also predict the effect on consumers' surplus of, for example, employing a particular functional form or treatment of travel time. Thus, the consumers' surplus figures from travel cost studies are unlikely to be random numbers with no link to the value of a site: this is reckoned to be of some comfort to policy-makers wishing to use such figures.

The indirect valuation methods covered in this section have the advantage that inference is based on actual market behaviour, so that the biases associated with direct valuation methods such as contingent valuation are not a problem. Indirect methods as a group do, however, have their own set of disadvantages. First, with particular reference to the TCM, the values estimated are not only just use values, they are the subset of use values which consist of tourist visits. They cannot account for either the essential services provided by ecosystems in terms of stabilization, resilience to shocks, and assimilation of undesirable substances, or the actual and potential medical uses which diverse flora and fauna serve. The methods, moreover, apply only to ecosystems that have scenery or wildlife sufficiently spectacular to attract visitors. If an inaccessible or unremarkable ecosystem attracts no visitors, then no value can be attached to it, or rationale for its preservation derived, using the TCM.

Ethicists and philosophers have made the argument that the valuation of biodiversity in monetary terms is nonsensical, since it implies a trade-off between the survival of a species and some quantity of a commercially traded good. The argument would certainly be persuasive if a monetary valuation did indeed reveal a trade-off in circumstances where no trade-off was possible (all species were assigned the absolute right of survival, as they might be in a biocentric perspective). But it is worth underlining the fact that monetary valuation does not necessarily imply that individuals are willing to make trade-offs of this sort. Many individuals would no sooner trade off the life of a

non-human organism against some traded good than they would trade off the life of a human. There are resources that are perfect complements to all other resources, whether because they are necessary to the production or consumption of all other resources or because people refuse to trade them off for moral, religious or ethical reasons.

It is worth adding that rejection of valuation overlooks the fact that it can be a more effective means to the end of conservation than an appeal to moral principles. At present, species are being lost at a rate of around 1–11% per decade (Reid 1992). Arguably, it is not the over-application of economic criteria to biodiversity and ecosystems, but the failure to apply them consistently which leads to this destructive and unsustainable state of affairs. Destruction of the forest can thus be objected to purely on the grounds of productive efficiency without recourse to either consumer valuation or ethics. If, alternatively, it can be shown that the ongoing consumer surplus from an ecosystem is greater than the potential return from its destruction, then this also provides concrete grounds for its defence. The grounds are purely in terms of human interest, and these being the terms in which policy-makers are accustomed to reasoning, are more likely to achieve positive results for conservation.

Destruction of ecosystems can occur when poor countries cannot justify the investment in conservation, even when the return is high. Eating the seed grain with unsustainable land use can be rational if problems of survival are so acute that the future carries virtually no weight in the decision-making process. Given that many of the benefits of biodiversity preservation are international and global, while most of the costs are direct and local, indirect valuation has an important role to play in highlighting the extent to which international institutions might be expected to finance conservation.

12.3.4 Production function approaches

In Chapter 12.2 it was noted that many biological resources and natural systems were being used directly in production as inputs or used indirectly in the sense that ecological functions and resources were supporting or protecting economic activity. Where such values are reflected in market prices and behaviour, then the various 'revealed preference' approaches suggested in the previous section may be adequate as valuation techniques, all of which use information about a marketed good to infer the value of a related non-marketed good. The previous section discussed travel cost and recreational demand which are examples of this form of surrogate market valuation that attempt to estimate the derived demand by households for environmental quality.

In this section, we are interested in another type of surrogate market valuation that is particularly useful for the valuation of non-marketed values associated with

biological resources and ecosystems that protect or support economic activity. This is the production function approach.² It consists of a two-step procedure. First, the physical effects of changes in a biological resource or ecological function on an economic activity are determined. Second, the impact of these environmental changes is valued in terms of the corresponding change in the marketed output of the corresponding activity. In other words, the biological resource or ecological function is treated as an 'input' into the economic activity, and like any other input, its value can be equated with its impact on the productivity of any marketed output.

More formally, if Q is the marketed output of an economic activity, then Q can be considered to be a function of a range of inputs:

$$Q = F(X_1 \dots X_k, S) \quad (4)$$

For example, a common ecological function of mangroves is the support of offshore fisheries by serving both as a spawning ground and as a nursery for fry. The area of mangroves in a coastal region, S , may therefore have a direct influence on the catch of mangrove-dependent species, Q , which is independent from the standard inputs of a commercial fishery, $X_1 \dots X_k$. Including mangrove area as a determinant of fish catch may therefore 'capture' some element of the economic contribution of this important ecological support function.

Applying the production function approach to the various indirect use values of biological resources and systems may prove a useful method of estimating these non-marketed – but often significant – economic values. However, it is extremely important that the relationship between any environmental regulatory function and the economic activity it protects or supports is well understood.

² The production function approach discussed here is related to the *household production function* approach, which is a more appropriate term for those surrogate market valuation techniques based on the derived demand by households for environmental quality. That is, by explicitly incorporating non-marketed environmental functions in the modelling of individuals' preferences, household expenditures on private goods can be related to the derived demand for environmental functions (Bockstael and McConnell 1981; Smith 1991). Some well-known techniques in applied environmental economics – such as travel cost, recreation demand, and hedonic pricing models (see previous section) – are based on the household production function approach. The *dose-response technique* is also related to the production function and household production function approaches; however, dose-response models are generally used to relate environmental damage (i.e. pollution; off-site impacts of soil erosion) to loss of either consumer welfare (i.e. through health impacts) or property and productivity (i.e. through damage to buildings, impacts on production).

Mäler (1991) distinguishes between applications of the production function approach. When production, Q , is measurable and either there is a market price for this output or one can be imputed, then determining the marginal value of the resource is relatively straightforward. If Q cannot be measured directly, then either a marketed substitute has to be found, or possible complementarity or substitutability between S and one or more of the other (marketed) inputs, $X_1 \dots X_k$, has to be specified explicitly. Although all these applications require detailed knowledge of the physical effects on production of changes in the resource, S , and its environmental functions, applications that assume complementarity or substitutability between the resource and other inputs are particularly stringent on the information required on physical relationships in production. Clearly, co-operation is required between economists, ecologists and other researchers to determine the precise nature of these relationships.

Applications of the production function approach may be most straightforward in the case of single use systems, i.e. resource systems in which the predominant economic value is a single regulatory function, or a group of ecological functions providing support or protection for an economic activity in concert. For example, Ellis and Fisher (1987) use this approach to model explicitly the environmental function of Gulf Coast estuarine and wetland systems in support of the commercial blue crab fishery. Taking the sum of consumers' and producers' surpluses as the measure of economic value, they hypothesize that an increase in wetland area increases the abundance of crabs and thus lowers the cost of the catch. The value of the wetlands' support for the fishery – which in this case is equivalent to the value of increments to wetland area – can then be imputed from the resulting changes in consumers' and producers' surplus.

In the Ellis and Fisher model, equation (4) above assumes the specific Cobb-Douglas form

$$Q = AX^a S^b, \quad (5)$$

where Q is the quantity of crab catch in pounds, X is effort measured by traps set and S is area of wetlands. The corresponding cost function is:

$$C = WA^{-1/a} S^{-b/a} Q^{1/a}, \quad (6)$$

where W is the unit cost of effort and S is determined exogenously. Assuming an iso-elastic demand for crabs and either private ownership or optimal public management (i.e. price equals marginal cost in both cases), Ellis and Fisher solve the two-equation model for the incremental value of the wetlands' support function.

However, employing the Ellis and Fisher model for the blue crab fishery, Freeman (1991) has made the important

additional point that the values imputed to the wetlands are influenced by the market conditions and regulatory policies that determine the conditions of access and rate of utilization of the fishery. For example, under open access, rents in the fishery would be dissipated, and price would be equated to average and not marginal costs. As a consequence, producer surplus is zero and only consumer surplus determines the value of increased wetland area. When the demand for crabs is inelastic, the social value of an increase in area is higher under open access than under optimal regulation, whereas the wetlands are more valuable under optimal regulation when demand is elastic. This result stems from the role of price changes in allocating welfare gains between producers and consumers: in the case of optimal regulations, part of the consumers' gain is a transfer from producer surplus, whereas under open access and zero producer surplus, any reduction in the price of fish associated with the average cost curve shifting down (in response to an increase in wetland area) results in a gain in consumer surplus and increased wetland value.

Freeman also calculates the social value of the marginal product of wetland area, which is given by:

$$\text{VMP}_S = bPQ/S, \quad (7)$$

where P is the price of crabs. As optimal regulation should lead to a higher price than open access, an inelastic demand means that VMP_S is higher under optimal regulation.

These different impacts of market conditions and regulatory policies for the production-function approach to valuing biological resources and systems are common, where there is open access exploitation and imperfect markets for resources. As argued by Barbier (1994b), this may be a prevalent feature of resource systems in tropical regions. In the case of multiple use systems – i.e. resource systems in which a regulatory function may support or protect many different economic activities, or which may have more than one regulatory ecological function of important economic value – applications of the production function approach may be slightly more problematic. In

Box 12.3-1: Economic value of mangrove system, Bintuni Bay, Irian Jaya, Indonesia.

Ruitenbeek (1992) uses a modified production function approach to evaluate the trade-offs between different forestry options for a mangrove system in Bintuni Bay, Irian Jaya, Indonesia. The options range from preserving the mangroves through a cutting ban to various forestry development options involving partial, selective and clear-cutting operations. An important feature of the analysis is that it tries to incorporate explicitly the linkages between loss of mangroves and their ecological functions and the productivity of economic activities. For example, the mangroves may support many economic activities, such as commercial shrimp fishing, commercial sago production and traditional household production from hunting, fishing, gathering and cottage industry; they may also have indirect use value through controlling erosion and sedimentation, which protects agricultural production in the region; and they have an indirect role in supporting biodiversity. To the extent that the ecological linkages in terms of support or protection of these activities are strong, then the opportunity cost of forestry options that lead to the depletion or degradation of the mangroves will be high. Thus, the 'optimal' forest management option – whether clear cutting, selective cutting or complete preservation – depends critically on the strength of the ecological linkages.

In the absence of any ecological data on these linkages, Ruitenbeek developed several different scenarios based on different linkage assumptions. This essentially amounted to specifying the relationship between Q and S in the production function for each productive activity at time t , Q_{it}

$$Q_{it}/Q_{i0} = (S_{t-\tau}/S_0)^a,$$

where S_t is the area of remaining undisturbed mangroves at time t , and a and τ are impact intensity and delay parameters respectively, $Q_{i0} = Q_{it}(t=0)$ and $S_0 = S_t(t=0)$. For example, for fishery–mangrove linkages, a moderate linkage of $a = 0.5$ and $\tau = 5$ would imply that shrimp output varies with the square root of mangrove area (e.g. a 50% reduction in mangrove area would result in a 30% fall in shrimp production), and there would be a delay of 5 years before the impact takes effect. If no ecological linkages are present, i.e. there is no indirect use value of mangroves in terms of supporting shrimp fishing, then $a = 0$. At the other extreme, very strong linkages imply that the impacts of mangrove removal are linear and immediate, i.e. $a = 1$ and $\tau = 0$.

The results of the analysis are depicted in the following table. Based on this outcome, Ruitenbeek concluded that the assumption of no environmental linkages is unrealistic for most economic activities related to the mangroves. Moreover, given the uncertainty over these ecological linkages and the high costs associated with irreversible loss if environmental linkages prove to be significant, then only modest selective cutting (e.g. 25% or less) of the mangrove area was recommended.

Box 12.3-1 cont.

Indonesia – total economic value of a mangrove system under varying environmental linkages

Economic value of Mangrove System, Bintuni Bay, Irian Jaya, Indonesia

(Net present value in billions of 1991 Rp; 7.5% discount rate) 2000 Rp = US\$ 1

Environmental linkages – none to very strong

- A = 20 year clear cut of mangrove forest
 B = 30 year clear cut of mangrove forest
 C = 80% selective cut of mangrove forest
 D = 40% selective cut of mangrove forest
 E = 25% selective cut of mangrove forest
 F = Ban on cutting of mangrove forest

Total net benefits include economic returns from (a) woodchip production from mangrove forest cutting, (b) commercial shrimp and by-catch fish production, (c) commercial sago production, (d) traditional household production from hunting, fishing, gathering and manufacturing, (e) imputed benefit of erosion control, and (f) capturable biodiversity.

particular, assumptions concerning the ecological relationships among these various multiple uses must be carefully constructed (see Box 12.3-1).

There are clearly major difficulties in specifying ecological-economic relationships for the application of the production function approach to estimating indirect use values in multiple use resource systems. Two major problems are the 'double-counting' and 'trade-offs' between various direct and indirect use values, which arise whenever

analysts attempt to 'aggregate' the various direct and indirect use values arising from multiple use resource systems.

Aylward and Barbier (1992) provide an example of both on-site and off-site double-counting in terms of the nutrient retention function of a coastal wetland. Coastal wetlands often absorb organic nutrients from sewage and other waste emitted into waterways further upstream. Suppose that the nutrients held by the wetland are indirectly supporting both shrimp production within the wetland area and the growth

of fish fry that supply an offshore fishery. If the full value of the shrimp production is already accounted for as a direct use value of the wetland’s resources, adding in the share of the nutrient retention service as an indirect value and aggregating these values would double-count this indirect use. In other words, the value of shrimp production already ‘captures’ the value-added contribution of nutrient retention. Trade-offs between two or more indirect use values of a given ecosystem may also occur. For example, Barbier *et al.* (1991) illustrate why it is necessary to account for such trade-offs in their analysis of the Hadejia-Jama’are floodplain in Northern Nigeria (Table 12.3-1). The floodplain supports a number of important agricultural, forestry and fishing activities within the area of natural flooding. The floodplain also contributes to the recharge of groundwater, which is in turn drawn off by numerous small village wells throughout the region for domestic use and agricultural activities. However, concerns have recently been expressed about the excessive water use of pump-irrigated wheat production within the floodplain. Increasing use of the floodplain water to support this activity may mean less water available for natural groundwater recharge – and thus for village wells outside the floodplain. If there are trade-offs between the two environmental support functions, then adding the full value of the wetland’s contribution to pump-irrigated wheat production within the floodplain to the full value of groundwater recharge of wells in neighbouring regions would overestimate the total benefit of these two environmental functions.

In fact, Barbier *et al.* (1991) were unable to value the contribution of groundwater recharge from the floodplain to economic activities in neighbouring regions. However, they were able to use a hydrological model of the wetlands

to estimate the productivity of agriculture, fuelwood and fishing activities within the floodplain area, and to compare the results with the returns per cubic metre of water diverted to an upstream irrigation project (see Table 12.3-1). Moreover, the floodplain benefits were adjusted for the ‘unsustainability’ of much pump-irrigated wheat production within the flooding area. The results suggest that, even without considering the economic benefits of the groundwater recharge function, diverting water for upstream development does not make much economic sense if it is detrimental to the natural flooding system downstream. These examples illustrate some important uses as well as limitations of the production function approach to economic valuation of biological resources and systems. Further examples of this approach can be found in Chapter 12.5.

Finally, dose-response models rely on tracing the effect of physical changes in environmental characteristics on marketed goods and services. A key intermediate stage in this is the behavioural response of producers to the change in the environment. Suppose that farmers in the USA find that higher tropospheric ozone levels are depressing yields of a particular crop due to foliar damage. These farmers may simply opt to produce less of this crop; or they may opt to grow different, less sensitive (but also, one assumes, less profitable) crops. This behavioural change must be captured in the dose-response model. One way of accomplishing this is the econometric route discussed above. A powerful alternative is mathematical programming models, the simplest (and most widespread) of which are linear programming (LP) routines. LP allows producers to find their profit maximizing output mix under a very wide range of price information and physical limits

on production. These limits can include those set by environmental conditions. For a full discussion of the relative merits of LP and econometric approaches to dose-response models, see Hanley and Spash (1994).

12.3.5 Revealed preference and opportunity cost

We conclude by summarizing the remaining widely used revealed preference methods, most involving some estimate of opportunity cost for another recent review see Filion and Adamowicz (1994).

12.3.5.1 Change in productivity method

If forests that are conserved as biodiversity habitats contribute to agricultural productivity through soil and water conservation, windbreak function and flood control, the loss of forests would result in a change (fall) in agricultural productivity downstream. The opportunity cost, or net value of the lost production (quantity times price minus saved production cost), constitutes a measure of the watershed (use) value of habitats to agriculture. The valuation of lost output due to deforestation or gain of output due to reforestation is done by applying market prices to the estimated output change. Any change in the cost of production is deducted from the change in gross value to obtain the net value of productivity changes which constitutes the true value of the forests' environmental services to agriculture. Indeed, in human welfare terms, the change in net social benefit resulting from environmental (or other) change is measured by the sum of the changes in producer surplus (profit) and consumer surplus (net consumer satisfaction). It must be stressed that this is the correct measure of welfare change due to environmental (or other) change, regardless of which method of valuation we use. All valuation methods aim to ascertain peoples' willingness to pay for an environmental improvement or to avoid an environmental damage or willingness to accept compensation to tolerate an environmental damage. In the example of agricultural production loss due to deforestation, the lost profit or producer surplus represents farmers' maximum willingness to pay to avoid the damage (or to accept to tolerate it); the lost consumer surplus represents the consumers' maximum willingness to pay for the same purpose.

The productivity change method can be used to obtain measures of most of the forests' direct and indirect use values, including timber production, non-timber forest products, tourism, water and soil conservation, etc. For example, the value of the ecological function of a forest in the catchment area of a hydroelectric dam can be measured by the net value of the change in the hydropower production due to sedimentation, traceable to change in the forest cover. Similarly, the net value of lost water-based

transport services or of tourist visits are measures of the value of the corresponding services of the forests.

12.3.5.2 Change in earnings method

This is very similar to the change in productivity approach except that we estimate directly the impact of the habitat loss on earnings (incomes or wages). In the case of farming we may estimate directly the change in farming incomes through econometric estimation of agricultural profit functions. In the case of workers who lose days of work due to environmental or related health damage, we can use the lost earnings as a measure of the value of the damage (or the affected people's willingness to pay to avert it).

12.3.5.3 Defensive or preventive expenditures method

This method measures people's valuation of the ecological services of the forests and other habitats by observing how much people are actually spending to prevent its loss or to defend themselves from the consequences of its loss. Farmers, for example, may contribute to a forest conservation or reforestation fund or they may defend their fields against soil loss through terracing or against floods through dikes and drainage systems. The observed defensive (or preventive) expenditures provide a measure of the farmers' valuation of the relevant ecological service of the forest. This method of valuation is applicable to forest services for which the beneficiaries (victims) perceive the benefits (damages) and take steps to secure (prevent) them. It suffers from a number of limitations stemming from its implicit assumptions that (a) actual preventive or defensive expenditures are representative of the affected population; (b) that environmental benefits and costs are perceived and responded to without undue delay; (c) preventive and defensive expenditures are effective and worth doing, and (d) there are no capital constraints and capital market imperfections that prevent a response. These are serious limitations and apply equally to the related method of replacement cost.

12.3.5.4 Replacement cost method

In many cases people may allow the environmental service of the forest to be lost and the damage (e.g. soil loss) to occur and attempt to replace or restore productivity through the increase of other inputs (e.g. fertilizer or irrigation). Similarly, hydropower lost to sedimentation may be replaced by the construction of another hydrodam or a coal-powered station. Tourist enterprises may attempt to restore lost recreational services of forests by planting trees or relocating to another area. The relocation cost method is a variant of the replacement cost method. By directly observing how much people are spending to replace the lost forest service or to relocate to avoid the damages from its loss, we can arrive at a judgement (or a monetary measure) of its value. It must be stressed that

this is a minimum or lower bound use value and it certainly does not include option or existence value. All limitations discussed in connection with the preventive/defensive expenditures method apply also to the replacement/relocation method.

12.3.5.5 Substitution or proxy method

This is closely related to other revealed preference methods but it is distinct in that it is not based on observed behaviour but on a surrogate market, the market of the closest substitute. The value of fuelwood to users is approximated by the price of the next best alternative (e.g. kerosene of equal calorific value; the value of soil loss by the cost of fertilizer needed to replace it; the value of non-marketed forest products such as fruits and medicines, by their marketed substitutes). Similarly, the value of a watershed in terms of regulation of water flows and water storage can be approximated by the cost of construction and operation of a dam that performs similar functions (minus any other economic benefits, plus any environmental costs related to the dam). But since we cannot directly observe the 'price' of the dam as we do with kerosene or fertilizer, this example fits better in the following closely related valuation method.

12.3.5.6 The shadow project method

The shadow project is an institutional judgement about the replacement cost of environmental assets or services. A particular environmental service of the forest is valued by designing and costing one or more shadow projects that provide for substitute environmental services to compensate for the potential loss. A plantation, a dam, a zoo, a park, a gene bank, etc., are some of the shadow projects that could be designed and costed as devices for valuing particular services of a habitat. This presupposes that it is feasible to replace damaged environmental services; a very strong assumption when it comes to complex ecological systems and poorly understood hydrological and atmospheric effects, and totally inappropriate in the case of species extinction. There are, however, shadow projects that can fully compensate for natural habitat loss as when another natural habitat of similar attributes under imminent threat of destruction could be saved in exchange. The cost of saving the latter can be used as a proxy for the value of the former. (Of course, ideally one may wish to try to preserve both).

From the standpoint of valuation, the cost of the project that fully compensates for natural resource injury or conversion will be no less than the minimum acceptable monetary compensation (i.e. willingness to accept). Determining the project that compensates exactly for natural resource loss or injury presents interesting ecological and public choice problems.

12.3.5.7 Compensation cost method

When a shadow project is not simply hypothetical (a valuation device), but actually serving also as a compensation device, the shadow project becomes a means of operationalizing the concept of sustainability at the individual resource or project level. In terms of project appraisal, while the hypothetical shadow project affects only the economic analysis of the project, the actual shadow project affects both the economic and the financial analysis. All the limitations discussed above apply plus the fact that compensation projects are likely to have their own adverse environmental impacts that should be fully costed and compensated for. Despite its limitations, the compensation approach when properly applied is both a useful valuation device and an instrument for internalizing the environmental costs of projects that result in habitat loss; where compensation is infeasible or uneconomic, the project is rejected.

12.3.5.8 Benefits transfer

Finally, benefits transfer is currently being argued by some to offer the potential to estimate economic values more quickly and less expensively than through the methods discussed in this Chapter (we are indebted to Fern Filion for the information reported in this subsection). Benefits transfer is accomplished by using values estimated from previous economic studies (usually referred to as results from a 'study site') and applying them to current policy and programme needs (usually referred to as a 'policy site'). For the estimates at the study site to be transferable, it must be possible to identify a number of valuation studies for which the 'study site' and 'policy site' characteristics are similar regarding the biodiversity in question. This matching of study and policy sites depends on establishing an explicit transfer protocol.

One attempt to do this is an initiative by Environment Canada with the US EPA to establish an Environmental Valuation Reference Inventory (EVRI). The initiative includes the designing and testing of a valuation database and defensible transfer protocol in support of benefits transfer in biodiversity conservation. As with the revealed preference methods reported in this Chapter, benefits transfer uses existing observations (though not necessarily observations on existing markets) to estimate the value of non-marketed resources. Moreover, as with hedonic pricing methods it assumes sufficient similarity in the supply and demand functions in the study and policy sites to make the transfer credible. This is a very stringent condition. While the approach has the attraction of being very low cost by comparison with other methods it cannot avoid the biases in those other methods, and it can only be as useful as the similarity condition allows.

12.3.6 Concluding remarks

To summarize the main points in this Chapter:

- **Valuation** is a method for determining the importance of environmental consequences of economic activity that are not taken into account in market transactions.

- Valuation makes it possible for resource users and environmental authorities to make informed decisions about the allocation of resources to biodiversity conservation. However, valuation does not necessarily imply that resource users should always trade off biological resources and commercially traded goods. Some individuals would no sooner trade off the life of a non-human organism against some traded good than they would trade off the life of a human. There are resources that are **perfect complements** to all other resources, whether because they are necessary to the production or consumption of all other resources or because people refuse to trade them off for moral, religious or ethical reasons.
- Biodiversity is a **public good**. It is therefore **non-exclusive** and **non-rival** in consumption, at least up to some capacity constraint. That is, up to a point the addition of more people does not reduce the benefits to any user. Nor does it exclude any other user. However, beyond that point the costs of additional people may increase very sharply.
- The public good nature of biodiversity complicates valuation. While the information requirements are higher, the reliability of data is lower, and people have a strategic interest in understating their willingness to pay to acquire benefits (the **free-rider problem**).
- There are two main approaches to estimating the value of non-marketed environmental effects of economic activity: (a) the use of **surrogate markets** to **reveal preferences** of resource users, and (b) the use of **simulated markets** to get resources users to **state preferences**. The main examples of these approaches are described in the Chapter.

12.4 The problem of risk and uncertainty

12.4.1 Distinguishing risk and uncertainty

Many of the effects of the reduction in biodiversity, in both the short and long term, are characterized by incomplete information. When individuals and societies value such resources they often do so in the knowledge that their understanding of the effects of their loss is imperfect. Indeed, people's understanding of the future effects of biodiversity loss is, if anything, less than their understanding of the future effects of climate change. How does this affect their valuation of biological resources? This chapter considers the ways in which incomplete information influences both the valuation of biodiversity and the decision-making process.

Economists typically distinguish between two classes of incomplete information: 'risk' and 'uncertainty'. The outcome of an action is said to involve risk where:

- the set of all possible outcomes of that action is known; and

- the probability distribution of all possible outcomes is also known.

By contrast, the outcome of an action is said to involve uncertainty when:

- the set of all possible outcomes of that action is unknown; and/or
- the probability distribution of the outcomes of the action is unknown (Dow 1993).

This chapter considers how the valuation of biodiversity is affected by incomplete information of each type, and hence how decisions involving incomplete information are made.

Most scientists would probably argue that biodiversity loss is characterized more by uncertainty than by risk. However, economic analysis deals more with risk than with uncertainty. Indeed, the theory of decision-making under uncertainty is much less well developed than the theory of decision-making under risk. The dominant approach to the analysis of risk in economics is the 'expected utility' approach by which individuals are assumed to evaluate a risky prospect in terms of the mathematical expectation of the value or utility to them of the prospect. The approach is described in Box 12.4-1. How well this approach explains real attitudes to risk has long been disputed. The empirical evidence suggests that many of the fundamental assumptions or axioms of the approach do not reflect reality. There is evidence, for example, that individual attitudes to risk are highly sensitive to income, and hence that attitudes to risk are not nearly as consistent as is assumed in the expected utility approach. People tend to be risk averse at low levels of income and risk averse or risk loving at high levels of income (Friedman and Savage 1948). While there have been no studies of attitudes to the particular risks associated with biodiversity loss, this observation would indicate that people place a lower weight on the biodiversity risks of economic activity the more affluent they become!

People also turn out to have asymmetric attitudes to gains and losses. Three such effects turn out to be important to the valuation of biodiversity: the reference point effect, preference reversal, and differences between willingness to pay (WTP) and willingness to accept (WTA). Empirical research has shown that individual decisions in the face of risk are frequently based on a reference point, usually represented by the initial endowment or status quo. Prospect theory (Kahneman and Tversky 1979) suggests that outcomes are interpreted by agents in terms of the reference point of their current asset position. It emphasizes the relevance of loss aversion. The aggravation experienced as a consequence of a loss often appears to be greater than the increase in utility due to a

gain of the same amount (the utility function is steeper for losses than for gains). Experimentally, similar behaviour has been observed when two prospects are designed in such a way that one implies a high probability of obtaining a modest gain, and the other implies a low probability of a remarkable gain. In this case people systematically choose the less risky situation in a direct choice (reveal a higher WTP for it), but place a higher value on the second alternative (reveal a higher WTA for it) if they were to sell it.³ What makes this behaviour important in the context of the valuation of biodiversity is that it suggests that individuals might be expected to assign much greater weight to the loss of a biological resource (say a species) than they would to an equivalent gain. This effect has not, however, been tested in work on the valuation of biodiversity loss.

Another source of difficulty for the expected utility approach is that empirical evidence suggests that attitudes to different prospects may not be independent, as is assumed in the approach. The famous Allais paradox,⁴ for example, turns out to be a special case of a general pattern known as ‘common consequence effect’. This holds that if there are only two options of equal probability, the better off individuals would be in the event of one option, the more risk averse they became over the other (see, for instance, MacCrimmon and Larsson 1979; Kahneman and Tversky 1979; Karmarkar 1974, 1978; McCord and de Neufville 1983, 1984).

³ This phenomenon was first reported by psychologists Slovic and Lichtenstein (1971). Further evidence has been provided by Lindman (1971), Mowen and Gentry (1980), Pommerehne *et al.* (1982), Reilly (1982) and Berg *et al.* (1983).

⁴ This is one of the best-known examples of empirical evidence against the expected utility model. The paradox can be illustrated by the following example (Machina, 1989; p. 22). The problem involves obtaining the subjects’ preferred option from each of the following two pairs of gambles :

- a₁:

1.00 chance of US\$1 000 000
- versus
- a₂:

0.10 chance of US\$5 000 000
0.89 chance of US\$1 000 000
0.01 chance of US\$0
- and
- a₃:

0.10 chance of US\$5 000 000
0.90 chance of US\$0
- versus
- a₄:

0.11 chance of US\$1 000 000
0.89 chance of US\$0

According to the expected utility hypothesis, a risk averse individual (relatively steep indifference curves) would prefer a₁ in the first pair and a₄ in the second pair, while a subject with relatively flat indifference curves would choose the gambles a₂ and a₃. However, it has been found that most subjects choose a₁ in the first pair and a₃ in the second. This implies that indifference lines are not parallel but rather that they ‘fan out’.

It is also now well understood that the power of the expected utility hypothesis declines as the probabilities of outcomes tend to unity or to zero. In the former case the probability of an ‘almost sure’ event tends to be approximated by certainty. In the latter case, people facing a ‘very unlikely’ event tend either to overestimate the probability or to identify it with zero. What this means is that for very low probabilities the weighting function is not defined. In the liability insurance markets it has been found that for cases in which the probability is very low but the potential loss is very high insurers demand a risk premium that makes the rates exceed the expected losses. At the same time, the insured are willing to pay less than predicted by expected utility calculations (Katzman 1988). This aspect has been widely dealt with in the literature on environmental liability insurance (see, for instance, Farley 1982; Martz and Bryson 1983; Sterling 1984). Many of the risks associated with biodiversity loss, like the ‘risks’ associated with climate change, are potentially catastrophic but of low probability, and hence difficult to deal with in expected utility terms.

Finally, an important part of the difficulty in valuing the risks of biodiversity loss derives from the fact that biodiversity has many of the characteristics of a public good. Empirical differences in estimates of willingness to pay and willingness to accept may well reflect the reference point effect already described in this chapter, but they also reflect the valuers’ perception of the availability of substitutes for the resources under consideration . While considerable investment is now taking place in the development of private substitutes for at least the genetic and pharmaceutical properties of biological resources (through pharmaceutical research and development, biotechnology and the establishment of genetically defined intellectual property rights) there is little evidence that private substitutes can be found for the ecosystem functions lost in the process of species deletion.

In many situations the lack of information or insufficient experience do not allow individuals to know the probabilities to be attached to the different alternatives they face when making a choice. This kind of incomplete information is addressed in different ways in the literature. One approach, due to Savage (1954), is to use subjective expected utility. In this approach decision-makers handle the lack of information by formulating subjective opinions about the likelihood of the future consequences of their decisions. In both the subjective and ordinary expected utility approaches decision-makers are led by the knowledge of a probability distribution – the only difference being that one distribution is subjective and the other objective. In the subjective expected utility approach, complete ignorance is addressed through the assignment of equal probabilities to all states of nature (the so-called principle of indifference or insufficient reason) (Arrow and

Box 12.4-1: The expected utility hypothesis.

The expected utility hypothesis arose from the observation of the inadequacy of the mere expected value as a measure for the attractiveness of a risky prospect.^a It is based on the assumption that individuals evaluate a risky prospect in terms of the mathematical expectation of the *utility* induced by the prospect. Thus, the attractiveness of a gamble offering the payoffs (x_1, \dots, x_n) with probabilities (p_1, \dots, p_n) is evaluated not by the expected value of the payoffs,

$\bar{x} = \sum_{i=1}^n x_i p_i$, but by the expected utility associated with those payoffs: $EU = \sum_{i=1}^n U(x_i) p_i$, where $U(\cdot)$ is what is termed a *von Neumann–Morgenstern utility function*.^b

The von Neumann–Morgenstern utility function assumes that preferences between prospects are transitive, continuous and independent,^c which makes it simple to characterize individual attitudes toward risk. If individuals are averse to risk, for example, their von Neumann–Morgenstern utility function is concave. Indeed, it is possible to refer to concavity, linearity, and convexity of the von Neumann–Morgenstern utility function as, respectively, risk aversion, risk neutrality and risk loving.

Concave utility function of a risk averter

Convex utility function of a risk lover

^a A *prospect* can be defined as a vector of probabilities that given states of the world will occur, with the corresponding vector of the outcomes associated with such states of the world.

^b It differs from the ordinal utility function of standard consumer theory in that the only transformations to which it can be subjected are positive linear ones, i.e. transformations that do not affect the shape of the function itself. The von Neumann–Morgenstern utility function $U(\cdot)$ can thus be replaced by any other $\bar{U}(\cdot)$ which is cardinally equivalent, in the sense that:

$$\bar{U}(\cdot) = \alpha U(\cdot) + \beta$$

for some multiplicative constant $\alpha > 0$ and an arbitrary additive constant β .

^c These three properties are embodied in the following axioms:

- (i) Complete-ordering axiom. For the two alternatives A and B one of the following must be true: the consumer either prefers A to B, prefers B to A, or is indifferent between them. The consumer's evaluation of alternatives is transitive if, preferring A to B and B to C, they prefer A to C.
- (ii) Continuity axiom. Let A be preferred to B and B to C. The axiom asserts that there exists some probability p , $0 < p < 1$, such that the consumer is indifferent between outcome B with certainty and a lottery (p, A, C) .
- (iii) Independence axiom. Let A be preferred to B, and C be any outcome whatever. If one lottery L_1 offers outcomes A and C with probabilities p and $1 - p$ respectively, and another L_2 offers the outcomes B and C with the same probabilities p and $1 - p$, the consumer will prefer L_1 .

Hurwicz 1972). But this presumes knowledge of the full range of possible outcomes, and the lack of such a knowledge is just what distinguishes genuine uncertainty from risk.

To account for genuine uncertainty (where the consequences of any choice are a function of unknown states of nature, and there exist no historical precedents and no *a priori* information on which to assign subjective

Box 12.4-2: Models of Fundamental Uncertainty.

As the loss of biodiversity involves fundamental uncertainty as distinct from risk, it is interesting to consider how this is currently being treated in the literature. Much of the development of Shackle's ideas is due to Vickers (1978, 1994) and Katzner (1989a, b). Earl (1983) absorbed it into the framework of behavioural economics, and it is also evident in other discussions of decision-making in ignorance (Georgescu-Roegen 1971; Arrow and Hurwicz 1972). Shackle's main concern is the agent's behaviour when facing a decision that is 'unique' and 'crucial': unique, in the sense that it relates to a particular decision-maker at a particular point of time, and to a set of characteristics unlikely to be replicated anywhere else in the system; and crucial in the sense that, once it is carried out, the pattern of the system as a whole is altered, and it is no longer possible to go back and repeat the same conditions. It is assumed that decision-makers imagine an incomplete collection of states of the world seen as possible consequences of their choice, and form non-probabilistic opinions about their possible occurrence. To each of such states decision-makers relate a measure of the degree of disbelief they would experience at their occurrence. The extent to which they believe an hypothesis may occur is bounded by their perception of what can happen, consistent with what they know about physical and economic processes.

The degree of disbelief is also referred to as *potential surprise*. There exist potential surprise density functions, each defined over possible outcomes associated with a particular decision, and all highly personal and subjective. Nonetheless, they are assumed to be precisely specified and well defined. These functions map all the subsets of the incomplete list of states of nature into a closed interval $\{0,1\}$, as with a probability distribution. Katzner (1986) introduced the concept of 'potential confirmation' as complementary to that of potential surprise. This is the proper expression of uncertainty, within the Shackleian framework, to be compared with probability. Both the set of imagined possible states of the world and the potential surprise function, depending on the individual's evolving informational status, are unique to each moment of historical time.

Despite the similarities, the potential surprise density function cannot be considered equivalent to an inverted probability density function (potential surprise is not equal to 'one minus probability'). Since the set of imagined possible states is not necessarily the complete collection of all possible outcomes, it need not be that the potential surprise associated with the residual hypothesis is unity. The individual's beliefs may be such that he does not exclude the occurrence of an unimagined outcome. Hence, the sum of the potential surprises of a hypothesis and its antithesis may be different from one (Katzner 1995).

The set of available choices is ordered by an 'attractiveness function' which is constructed by the decision-makers on the basis of their own cognition. It measures the extent to which each outcome gets the attention of the decision-maker and reflects both utility outcomes and potential surprise. Maximization of the attractiveness subject to the potential surprise density function forces the decision-maker to focus his attention on two particular outcomes: respectively the best and the worst among the least potentially surprising ones. The former is what Shackle refers to as 'focus gain', and the latter as 'focus loss' of a decision. They can be considered as the parallel, in a non-probabilistic context, of a choice's expected benefit and expected cost. So possible outcomes with high associated costs will be taken into more careful consideration the smaller is the potential surprise they involve. The introduction of a decision function over the set of pairs of focus gains and losses then permits the subject to make a choice from them.

probabilities to the different states of nature) some economists are developing alternative approaches. Much of this work is stimulated by the separate ideas of Shackle (1955, 1969), Abbott (1955) and Simon (1957) (see Box 12.4-2). The last two acknowledged that limits and lags inherent in individual learning process about the dynamic environment in which decisions are to be taken, resulted in a more limited rationality, usually referred to as *bounded rationality*. Such limitations force agents to pursue 'satisficing' rather than optimizing behaviour. On the other side, Shackle argued for a complete change in the decision model.

The treatment of uncertainty in the Shackle approach does not require estimates of the probability distribution of

outcomes. However, if (1) such estimates do exist and the problem has become 'routine' in the sense that all functions remain constant over time, and (2) none of the sources of bias discussed in the previous subsections are present, then the potential benefits and costs of a decision (what is referred to as its focus gain and focus loss) may approximate the expected benefits and costs of that decision in utility terms. If the set of possible outcomes of a decision and the probability distribution of those outcomes are both known, then the decision will certainly be routine in the sense of Shackle. In this case the outcome may very well be similar to the optimal outcome under an expected utility approach. However, if the decision-maker's attention is drawn to some particular outcome (as it tends to be in,

say, the aftermath of a disaster) then the decision-making process will become non-routine, and the Shackle outcome will be very different from the expected utility outcome. More importantly, the implicit valuation of the resources concerned will be different from the valuation derived from an expected utility approach. Indeed, the Shackle approach indicates that any valuation of biological resources will necessarily be highly context-dependent. It will depend less on the opportunity cost of committing the resource to some use, than on the range of factors that draw the decision-maker's attention to the particular use whose focus loss and focus gain are being evaluated.

12.4.2 Risk and uncertainty in environmental decision-making

If decision-makers face risky situations, then what criteria should they employ? A natural choice following on from expected utility theory is to make use of expected values, with some adjustment for risk aversion (or, less usually, risk seeking) on the part of those affected by the decision. Thus if a nuclear power station involves a quantifiable risk of serious leakage, and if monetary values can be placed on damages should leakage occur, then the expected value of the damages can be calculated as simply the product of the probability of an accident occurring and the value of damages should an accident occur. If expected values can be calculated for risky costs and benefits, then an 'expected net present value' for any project /policy where this information is available can also be calculated within the framework of cost benefit analysis (CBA). Risk attitudes are allowed for by either adjusting the discount rate upwards by a 'risk premium', if risk aversion is desired⁵; or by finding the 'certainty equivalent' of the expected damages (that certain level of damage which would give the same disutility as the uncertain, expected level of damage).

However, the empirical evidence on people's attitudes to environmental risk discussed above raises questions about the value of such an approach. For example, McDaniels *et al.* (1992) refer to 'dread' as the phenomenon which increases subjective risk assessments connected with, for example, nuclear power or toxic waste disposal; lower 'dread' events such as car accidents are subject to under-assessment of risks. Econometric analysis has shown that risk rating has a higher effect on willingness to pay for risk-reduction measures in infrequent high dread situations, than in frequent low dread situations. Unless the analyst has information on these subjective preferences, the outcome may be inefficient. Finding the public's perception of risk is in itself difficult: Loomis and du Vair (1993) show that different ways of portraying the same risk reduction to

individuals (in this case, from improving safety at hazardous waste sites) produce statistically different estimates of willingness to pay for the risk reduction.

Second, the expected utility framework may not describe very well how individuals rank or value risky alternatives. Evidence suggests that individuals value different sorts of risks differently, even if the expected values are equal. For example, the degree of familiarity and the extent to which respondents are 'in control' of the risk have been shown to be important (Knetsch 1993). Individuals are more averse to risks beyond their control (as are the risks of biodiversity loss or climate change) than they are to risks in their control. But their willingness to pay to avoid risks will be influenced by the degree to which they can capture the benefits of risk reduction: i.e. by the public good nature of the risk. Where they can capture the benefits of risk reduction, individuals tend to take actions that influence either the magnitude of (usually undesirable) events should they occur, or the probability that they will occur. The former action is termed 'self-insurance' and the latter 'self-protection'. Other species behave in the same way. Where they cannot capture the benefits of risk reduction, as in many publicly funded programmes to reduce the risks of, for example, carbon emissions, they tend to understate their willingness to pay for a reduction in risk.

The treatment of risk in project/policy appraisal has also been concerned with the extent to which individuals, firms or society as a whole can reduce risk by diversifying. This is easy to imagine for a financial investment: investing money in a single stock seems likely to be riskier than investing money in several stocks, having some regard for the expected covariance of their returns. The Capital Asset Pricing Model, one of the principal theories of finance, states that investors will only be rewarded by the market for that part of the risk which cannot be diversified away by holding an 'efficient' portfolio of assets. Swanson (1992) has likened the preservation of biodiversity to such a portfolio effect, and refers to this as an insurance service. If different species vary in their sensitivity to environmental change, then reducing the variety of species 'held' by society in its portfolio is akin to increasing the risk that society bears. Homogeneity increases risk, although it may also (as in agriculture) increase financial returns, at least in the short run. Increasing diversity reduces overall risk at the expense of lower financial gain, although, as the reader will be well aware by now, the true economic benefits of biodiversity preservation exceed those recorded in market transactions.

A second feature of risk reduction via diversification is the effect on the discount rate. Arrow and Lind (1970) argued that, as the number of people bearing a risk goes towards infinity, the risk premium each demands goes to zero. Since many, if not all, of the Earth's citizens bear the risks associated with biodiversity loss, it might be argued

⁵ See Hanley (1992) for a summary of the debate on whether or not this is good practice.

that those decisions about biodiversity preservation made using CBA should use a risk-free discount rate. This would be incorrect, however (Brown 1983). To the extent that the costs of biodiversity loss are non-rival in consumption (such as an increase in the threat of global extinction), then the number of persons bearing the loss has no effect on the cost to each in this worst of all cases. If this is accepted, then the risk premium should not be deducted from the discount rate.

In many cases uncertainty is such that we cannot calculate expected net present values (NPV) since the range of possible outcomes and/or their probabilities is unknown. In the case of the construction of a nuclear power plant, for example, a certain, scientifically calculated risk can be attached to the occurrence of a serious accident. The full consequences of such an accident, however, in terms of monetary loss, human suffering and duration of the effects, is necessarily uncertain. Likewise, the consequences of an action which causes loss of biodiversity may not be foreseen until after the action has been taken. (This necessitates particular care when the action will be irreversible). An example of unforeseen consequences is the experience of Bangladesh which, between 1977 and 1989, exported frogs for the growing Western (particularly American) market. By 1988 exports had reached 50 million per year, earning US\$10.5 million in foreign exchange. However, the fact that frogs, by eating waterborne paddyfield pests, performed an essential function, was not reflected in the market and was therefore overlooked. By 1989 when the government introduced a ban on exports, the frog population was estimated to have fallen to 400 million and, to compensate, farmers were importing \$30 million of the worst quality pesticides, annually. That the net economic effect of frog exports was negative, is plain. The damage to watercourses and health is unestimated.

The export of frogs from Bangladesh is an example of a decision without historical precedent. In Shackle's terms it was one in which the choice options, imagined states of the world, potential surprise function, utility and attractiveness functions were all peculiar to the decision moment. The decision involved fundamental uncertainty, and the actual outcome turned out to be very different from the expected outcome. The question considered below is what options were open to decision-makers if they had wished to take the fundamental uncertainty associated with the decision into account.

12.4.2.1 Scenario analysis

This involves taking each known state of the world, and calculating NPV assuming this state of the world actually exists. In this case, 'pay-offs' (that is, costs and benefits) must be calculable for each state of the world that it has been possible to identify. In practice, the analyst would limit attention to a subset of known states of the world,

choosing, perhaps, extreme values (pessimistic and optimistic) and values thought most likely. Different decision-theoretic rules such as maximin or minmax regret can be applied to such a pay-off matrix in order to identify the desired course of action.

12.4.2.2 Extended scenario analysis (sensitivity analysis)

This involves seeing by how much NPV changes as the state-of-the-world changes; particular attention is paid to that point at which NPV changes sign; and to determining the variable to which NPV is most sensitive. If uncertainty exists over many parameters of the decision, then the major weakness of sensitivity analysis is that it proceeds on a *ceteris paribus* basis.

12.4.2.3 Monte Carlo analysis

This involves specifying frequency distributions for each parameter, and then simulating simultaneous changes in all parameter values according to random sampling from these distributions.

12.4.2.4 Worst-case scenario

In this approach the worst case is assumed to be the true scenario. In this case, the highest level of environmental damage that could conceivably result from the loss of a habitat type in a particular country, for example, would be assumed to be the true level, and a CBA would be carried out on this basis. This effectively implies use of a maximin regret principle, which is similar to a precautionary principle.

12.4.3 The precautionary principle and safe minimum standards

Environmentalists often argue that where the costs of current activities are uncertain, but are potentially both very high and irreversible, society should take action before the uncertainty is resolved, since the costs of not taking action may well be greater than the costs of preventative or anticipatory action taken now (Taylor 1991). The policy of taking action before uncertainty about possible environmental damages is resolved has been referred to as the 'precautionary principle'. The principle is argued to have originated in Germany as the concept of 'Vorsorgeprinzip' (Haigh 1993), and has been defined in the Declaration of the Third Ministerial Conference on the North Sea as:

...action to avoid potentially damaging impacts of substances that are persistent, toxic and liable to bioaccumulate even where there is no scientific evidence to prove a causal link between effects and emissions (quoted in Haigh op.cit.).

The stress is thus on the avoidance of potentially damaging actions in the face of uncertainty about future

outcomes; a deliberate act of risk reduction. More recently, the principle has been broadened to include the concept of 'ecological space': that is, of not '...pushing all actions to the limits of ecological tolerance'. Haigh (1993) argues that instances of the precautionary principle (PP hereafter) being applied include the Montreal Protocol on substances *likely* to damage the ozone layer; the North Sea conference decision to reduce polluting inputs to the North Sea by 50% by 1995; and the EC agreement to reduce CO₂ emissions. Indeed, the 1874 Alkali Act, often cited as one of the first pieces of environmental legislation in the UK, did not insist on *proof* that gases discharged from factories actually caused deleterious health effects, before they could be subject to control. More recently in the UK, the 1990 White Paper, *This Common Inheritance* states the PP as a first principle of environmental policy.

The PP, which can be extended to many areas of environmental management, thus seems to be a widely accepted principle for wise environmental management. Indeed, it has also been argued to be an essential part of any sustainable development strategy, in the 1990 Bergen Declaration (signed by 84 countries as a follow-up to the Brundtland Commission report). The PP has also been advocated for decisions over the preservation of biodiversity (Myers 1992). However, two qualifications have emerged. First, the Rio summit called for all countries to apply the PP, but only '...according to their capabilities', implying that the costs of actions under the PP should be considered, and might be deemed too great for some (poorer) countries. Second, the UK Government in the 1990 White Paper referred to above, stated that the PP should only be applied '...if the balance of likely costs and benefits justifies it' (paragraph 1.18). There is thus some requirement for the benefits of implementing the PP to be in a sense proportional to the costs. This second restriction is rather more severe, since to apply it would involve some estimates of the probabilities of different possible outcomes being known, that these outcomes could be physically described, and that they could be valued in monetary terms. But if this were so, then a more formal application of cost-benefit analysis could guide policy analysis: the PP would be incorporated in the treatment of risk (for example, by giving greater weight to the worst possible outcomes).

However, it should be noted that some have taken acceptance of the PP to mean that society should have as a firm objective the total elimination of activities where uncertain environmental damages are involved (Taylor 1991). Examples of such bans do exist: for example, the banning of the disposal of radioactive wastes in the deep ocean, and the incineration of toxic wastes at sea. Alternatively, the PP could be taken to mean the minimization of inputs of any effluent to any ecosystem. However, the economist might worry that the costs of either banning the disposal or minimizing the input of

effluent would be disproportionately large, and incur unnecessarily high opportunity costs for society. For example, deciding to enforce a 50% reduction in fossil fuel emissions now, in line with the most pessimistic predictions about the damages associated with, and the extent of, global warming would involve very high costs in terms of losses in current social welfare. Accepting the PP also assumes that the worst environmental outcome will definitely occur, which as Grout (1981) has argued is unreasonable if this is only one of a (very large) number of possible outcomes.

There is a close link between the precautionary principle described above, and the safe minimum standards (SMS) approach, proposed by Ciriacy-Wantrup (1968) and Bishop (1978). The SMS approach involves setting quantitative and qualitative minimum limits for, in this case, biodiversity preservation. These limits are then upheld unless the social opportunity costs of doing so are 'unacceptably high'. What constitutes an unacceptable opportunity cost is to be decided either by policy-makers, on behalf of the electorate, or by the electorate directly through public forum. The SMS approach has been characterized as a means of minimizing maximum possible losses to society in the face of (1) uncertainty over the benefits of (biodiversity) preservation; and (2) the irreversible nature of environmental losses. Hanley *et al.* (1991) suggest that the existence of policies that protect a safety net of habitat types, such as the Sites of Special Scientific Interest in the UK, are an example of the SMS principle in use. Sites of Special Scientific Interest may be lost if the costs of preserving them are too high in terms of the government's conservation budget, but the presumption is in favour of their protection, regardless of any cost-benefit analysis. More generally, SMS scheme places the onus on those wishing to allow environmental losses to prove that the opportunity costs of preservation are 'too high'.

12.4.4 Concluding remarks

In summary, there are four points about the incomplete information associated with the effects of biodiversity loss that are important to the valuation of biological resources:

- Many of the short and long-term effects of the reduction in biodiversity are characterized by incomplete information. Two classes of incomplete information are considered: **risk** and **uncertainty**. Risk exists where the set of all possible outcomes of an action and the probability distribution of those outcomes is known. Uncertainty exists where the set of all possible outcomes of that action, and/or the probability distribution of the outcomes of the action is unknown.
- Some of the consequences of a change in biodiversity involves risk. Most consequences involve uncertainty,

particularly where the changes concerned are irreversible and the evolutionary response of the natural system is unpredictable.

- Consequences that involve risk may be commercially insurable. Consequences that involve uncertainty may not be commercially insurable. A **precautionary** approach to uncertain consequences is to protect the capacity of the system to absorb them.
- The ecological redundancy in current biodiversity has an **insurance value**, in that it enables the system to maintain the flow of ecosystem functions under changing environmental conditions. A precautionary approach is to apply **safe minimum standards** involving quantitative and qualitative minimum limits for biodiversity preservation. The **SMS** approach has been characterized as means of minimizing maximum possible losses to society in the face of (1) uncertainty over the benefits of (biodiversity) preservation and (2) the irreversible nature of environmental losses.

There are several reasons why treatment of the environmental 'risks' associated with biodiversity loss within expected utility framework is problematic. First, as mentioned above, even when the increase/decrease in risk that will result from an action is known, the device used to convey this risk to the individual in a valuation exercise can significantly affect the value that is placed on its reduction. The Loomis and du Vair study considers risk which is well defined, and for which the costs and benefits of reduction pertain to the individual concerned. But consistent responses cannot be obtained even for risks such as these. Valuations of increased risk due to biodiversity loss must necessarily be more vague still, both because of free-rider effects in the gains from reduced risk (the public good problem again) and because of uncertainty over the gains themselves. That is, the extent to which a given reduction in local biodiversity loss reduces global (and even local) risk is uncertain and therefore difficult to value, even in the absence of information constraints and problems of perception.

Maintenance of biodiversity does reduce risk. As species are progressively lost, the risk that some disaster threshold may be reached with the next loss is an increasing one. In agriculture, for example, genetic diversity in cultivated crops and reserve species ensures that yields may be maintained over a wider range of environmental conditions. However, conservation as a risk-reducing device has two features that set it apart from more common risk reducers such as financial insurance. These are the fact that many outcomes of biodiversity loss are fundamentally uncertain, and that biodiversity is a public good. The fact that the benefits of conservation do not all accrue to the conservationist means that the level of conservation

resulting from a cost-benefit exercise could be economically inefficient.

The irreversible nature of biodiversity loss and the uncertainty of its effects on future generations both favour adoption of the precautionary principle. Indeed, it is not wholly misleading, given the importance of biodiversity to life-support systems, to think of its conservation in terms of Pascal's Wager (as in Orr 1992). Pascal's Wager refers to a dilemma over whether or not to believe in God. In this case, the assumption is that the implication of believing is that one behaves virtuously and thus forgoes some wicked pleasures (!). Pascal's conclusion is that there is nothing to lose, and everything to gain, by believing in God. If one believes, and it turns out at the end of the day that God does not exist, then no damage has been done and life has moreover been lived virtuously (although, of course, at the cost of forgone wicked pleasures). If God does exist then eternal damnation has been escaped. Likewise, if ecosystems and biodiversity are conserved and it turns out that the risks from their destruction would not be so great after all, global society has still conserved valuable assets which yield much in terms of production and pleasure (although, by implication, we would forgo certain development benefits). If, on the other hand, it were to transpire that continued biodiversity loss spelt doom for life as we know it, then by conserving rather than destroying biodiversity, we have saved everything. The point should, however, be re-emphasized that, over the long run, preserving biodiversity *might* imply larger losses in welfare than it generates, especially if forgone development benefits turn out to be high and the importance of diversity turns out to be low.

12.5 The valuation of species and habitats: empirical results

12.5.1 Introduction

Our previous discussion of the available methodologies for the valuation of biodiversity have included occasional examples of value estimates for species, habitats and ecosystem functions. In Chapters 12.5 and 12.6 we focus on the results of empirical research on valuation. Given the nature of the research the results are far from systematic. Valuation research has tended to be driven by popular concern for charismatic mammals or birds, visually imposing habitats, and major pollution events such as the *Exxon Valdez* oil spill. Although the theoretical literature suggests the importance of refocusing on ecosystem functions, empirical research along these lines is still in its infancy.

Chapter 12.5 discusses estimates of the value of charismatic species and habitats arrived at through the use of both revealed and stated preference methods. Chapter 12.6 then considers estimates of the value of broader

ecosystem functions. The results discussed here derive from a wide range of valuation techniques. Our intention is more to give a sense of what may be achieved using these techniques, and what their limitations are, than to give credence to any one set of estimates.

Many biological resources are transacted directly on domestic or international markets. Indeed, commercial uses of resources are important for both developed and developing countries. This suggests that some direct use values of domesticated and wild resources will be reflected in the prices of ‘marketed’ goods and services. However, because governments and individuals can more readily perceive the economic value of marketed products (and services) of biological resources than the value of non-commercial and subsistence direct uses, the result can be a bias towards the development of the commercial use and exploitation of biological resources. This may mean not only that, for example, commercial fishing, forestry and agricultural operations may be preferred to subsistence operations but also that many natural ecosystems and habitats may be converted to other uses, including the cultivation and harvesting of domesticated species (see Box 12.5-1). The latter problem is particularly prevalent in tropical countries, where many of the world’s remaining

reserves of wild resources are under mounting pressure from habitat conversion and over-exploitation (see Swanson and Barbier 1992; Barbier *et al.* 1994 for further examples).

Table 12.5-1 offers estimates of the economic value of the direct use of wild resources in a variety of economic activities. These can be highly significant, even in developing countries. If proper accounting of these values occurs, then ‘sustainable management’ of wild resources and their habitats may make more economic sense. The result may be less conversion of natural areas to alternative uses. For example, Barnes and Pearce (1991) demonstrate that full consideration of the commercial and non-commercial use values of different wildlife management operations in Botswana, such as small-scale group harvesting, ostrich farming, crocodile farming, tourism, safari hunting and game ranching would make these various wildlife management options more economically attractive compared to using the same game areas for cattle ranching. Similarly, Barbier *et al.* (1991) show that the direct uses of the Hadejia-Jama’are floodplain in Northern Nigeria for fishing, fuelwood and recession agriculture – much of which is for subsistence consumption by rural households – appear to offer much higher economic returns when

Table 12.5-1: *Estimates of direct use value of selected wild resources in developing countries.*

Activity/Use	Estimated value (\$US)	Source
Pre-ban ivory exports, Africa	\$35–45 million/year	Barbier <i>et al.</i> (1990)
Tropical non-coniferous forest product exports	\$11 billion/year	Barbier <i>et al.</i> (1994b)
Fruit/latex forest harvesting, Peru	\$6330/ha	Peters <i>et al.</i> (1989)

Box 12.5-1: The value of gum arabic.

The gum arabic tree (*Acacia senegal*) is a naturally occurring species in the Sudano-Sahel region that serves a variety of valuable economic and ecological functions. The gum produced by the tree – the ‘gum arabic’ – is widely sought after in industrialized countries for use as an emulsifier in confectionery and beverages, photography, pharmaceuticals and other manufacturing industries. In addition, the *A. senegal* tree provides fodder for livestock, fuelwood and shade. There are also numerous indirect benefits associated with these trees; for example, its extensive lateral root system reduces soil erosion and runoff, as a leguminous tree it fixes nitrogen which encourages grassy growth for livestock grazing, it serves as a windbreak and is important in dune fixation. For these reasons, the tree is the preferred species in bush–fallow rotation and intercropping farming systems prevalent in the arid West of Sudan. On a larger scale, across the Sudano-Sahelian region, the gum arabic ‘belt’ acts as a buffer against desertification.

The choice by farmers in Sudan to incorporate gum arabic trees in their farming systems will depend on whether the above benefits from a gum arabic based system exceed those of alternative systems. The potentially high financial rate of return to a gum arabic-based farming system coupled with its important environmental benefits would seem to imply that such a system would be ideal for combating desert encroachment and rehabilitating the gum belt of Sudan. However, in recent decades, the real producer price of gum arabic in Sudan has fluctuated considerably, as has the relative price of gum to its competitor cash crops (sesame, groundnuts) and even food crops (sorghum, millet). Farmers' share of the export value of gum also remains low, which has been one reason for the recent increase in smuggling of gum to neighbouring countries.

An economic analysis was conducted of six representative cropping systems containing gum arabic cultivation in Sudan (Barbier 1992). The results are indicated in the following table.

Economic analysis of six cropping systems, Sudan (1989/90 Sudanese Pounds per Feddan, 10% Discount Rate)

	<i>Acacia senegal</i> ¹	Sorghum	Millet	Groundnuts	Sesame	All crops
BN	2 989.57	4 606.83	2 931.58	—	—	10 527.98
WN	3 923.82	—432.99	486.30	5 330.92	8 605.12	17 913.17

SK	882.99	1 644.44	—	13 109.44	13 776.95	29 413.82
ND	1 240.87	—	2 363.89	9 687.69	—	13 292.45
SD	1 884.02	3 830.80	3 775.60	9 715.61	—	19 206.03
All	2 412.27	2 392.83	9 460.92	9 467.67	16 656.25	

BN = Blue Nile Province, clay soils, largeholder;
WN = White Nile Province, sandy soils, smallholder;
NK = North Kordofan Province, sandy soils, smallholder;
SK = South Kordofan Province, clay soils, largeholder;
ND = North Darfur Province, sandy soils, smallholder;
SD = South Darfur Province, sandy soils, smallholder;
All = Average of all six systems.

1. Total NPV from gum, fuelwood and fodder, except for Blue Nile and South Kordofan (gum only).

Source: Barbier (1992).

Although the analysis shows that all six systems are economically profitable, the relative profitability of gum compared to other crops in each system is generally lower than that of other crops – except in the Tendelti system of the White Nile where field crop damage occurs frequently. In most systems there are initial losses due to the need to establish gum gardens before they begin producing. This would suggest that maintaining the real producer price of

Box 12.5-1 cont.

gum by removing distortions in the market, as was assumed in the analysis, is a necessary economic incentive to encourage gum cultivation. However, despite the lower relative returns to cultivating gum arabic, there are several reasons why converting land under *A. senegal* to cultivating annual crops may not be desirable:

- some land under *A. senegal* may not be suitable for growing annual crops, resulting in very low and fluctuating yields;
- fallowing land may be important to maintain its fertility; gum arabic is the ideal cash crop for this purpose;
- the environmental benefits of gum arabic trees (e.g. control of erosion/runoff, wind breaks, dune fixation, nitrogen fixation) were not included in the analysis, and these may be significant in maintaining the yields of field crops within the farming systems;
- the role of the gum belt in controlling desertification certainly is significant in supporting and protecting farmingsystems in the region, and although this collective benefit cannot be captured in an analysis of individual systems, traditional farming communities in the gum belt region are very much aware of this benefit;
- risk-averse farmers may desire some of their land to be held under gum cultivation, because the returns to gum – although lower than the maximum expected returns from the cash crops – may be less variable under stressful environmental and climatic conditions;
- gum cultivation provides cash income to farmers outside of the growing season for cash crops.

In other words, the estimated rate of return understates the value of this particular resource precisely because it does not take into account the indirect value of the resource in the provision of a range of ecological functions other than the gum itself.

compared to upstream irrigation developments that are diverting water away from the floodplain. Finally, Peters *et al.* (1989) have shown that in a Peruvian rain forest the discounted financial returns from non-timber harvesting of fruit and latex plus selective cutting of timber easily exceed the returns from alternative operations, such as clear-cutting timber, plantation cultivation and cattle ranching.⁶

Now consider the position in the more developed economies. The various valuation estimates of Table 12.5-2 reflect the fact that the use of natural areas and resources tends to differ between developed and developing countries. For example, Barbier (1994b) notes that many tropical wetlands are being directly exploited, often through non-marketed or 'informal' economic activity, to support human livelihoods, e.g. through fishing, hunting, fuelwood extraction, and so forth. If they occur at all, recreational use and tourism are generally limited in comparison. In contrast, in temperate wetlands direct exploitation to support livelihoods – except perhaps commercial fishing, forestry or hunting and trapping in some areas – is on the whole less important compared to recreational, tourism and amenity values.

Several studies have shown that recreational and other non-marketed direct use values derived from wild resources and ecosystems can be substantial in developed countries and often compare favourably with competing commercial uses of the same resource. Willis (1991), for example, estimated the total recreational value of the Forestry Commission estate of Great Britain to be around US\$79.5 million per year, whereas total annual timber sales from the estate amount to around US\$106.6 million. Hyde and Daniels (1988) also demonstrate that correct valuation and comparison of recreational use and timber production on public forest lands is important for determining the optimal use of these lands in terms of these competing market and non-marketed outputs. Similarly, Loomis *et al.* (1991) compare the economic benefits of deer hunting versus cattle ranching in the Sierra Nevada, California, through estimating the value of forage areas to deer hunters as opposed to ranchers. Coyne and Adamowicz (1992) applied the random utility model to the valuation of the site characteristics for alternative Bighorn sheep (*Ovis canadensis*) hunting sites. Data came from a mail survey of registered hunters in Alberta. This survey gave information on socioeconomic characteristics, home location of hunter, number of hunting trips, and choice of site. This gave 423 'choice occasions' when particular sites were chosen by particular hunters. A multi-nomial logit model (Greene 1990) showed that

⁶ Although widely cited, the valuation estimate of Peters *et al.* (1989) has been recently criticized by Godoy *et al.* (1993) for being inaccurate.

Table 12.5-2: Estimates of Direct Use Value for Selected Wild Resources in Developed Countries.

Activity/Use	Estimated value (\$US)	Source
All freshwater fish stocks, Norway	\$128–204/adult/year	Strand (1981a) ¹
Recreational sport fishing, USA	\$2 703–4 281/person/year	Bockstael <i>et al.</i> (1987)
Recreational moose hunting, Norway	\$296/hunter/year	Soedal (1989) ¹
Recreational elk hunting, USA	\$12.74–58.33/hunter	Brookshire <i>et al.</i> (1980)
Commercial marsh and estuarine fisheries, USA	\$317–845/acre	
Fur trapping in marshlands, USA	\$151–401/acre	Bergstrom <i>et al.</i> (1990)
Coastland wetlands site amenities, USA	\$1 992–23 848	Shabman and Bertelson (1979)
Wetlands recreation amenity, UK	\$100.5–210/visitor	Bateman <i>et al.</i> (1993)
Timber sales income, UK	\$106.6 million/year	
Recreational use of forests, UK	\$79.5 million/year	Willis (1991)
Timber stumpage value from public forests, USA	\$38.72–83.54/thousand board feet	
Recreation use of public forests, USA	\$16.24/recreation-visitor-day	Hyde and Daniels (1988)
Recreation value of wilderness areas, USA	\$76/visiting household/year	Walsh <i>et al.</i> (1984)

1. Summarized in Navrud (1991) and Navrud (1992: Ch. 6).

Source: see references.

hunters’ choice of site depended mainly on travel costs, total sheep population and crowding (number of hunters per unit area). This model also enabled the welfare effects of changes in these characteristics to be calculated. It was concluded that hunters would suffer a US\$7254 decrease in welfare per season if the resident sheep population fell by 10%. Complete closure of any site was also valued; these values ranged from around \$25 000 to \$4000 per season.

12.5.2 The value of genetic resources and biotechnology

Nearly all modern crop varieties and some highly productive livestock strains contain genetic material recently incorporated from related wild or weedy species, or from more primitive genetic stocks still used and maintained by

traditional agricultural peoples. Likewise, both cultivated and wild biota are important contributors to the pharmaceutical and health industries. Two-fifths of all modern US pharmaceutical products contain one or more naturally derived ingredients (Oldfield 1984). It has been estimated that at least half of the increase in agricultural productivity realised this century is directly attributable to ‘artificial selection, recombination and intraspecific gene transfer procedures’ (Woodruff and Gall 1992). What has already been called the *gene revolution* by genetic engineers and biotechnologists has created an important expectation about the scope for maintaining or even increasing agricultural productivity in a situation where the human population is forecast to double in size by the end of the next century.

In agriculture, genetic resources are used in two ways: (1) selecting certain species or populations for domestication and cultivation, and (2) genetically improving economically important species. The vulnerability of agriculture due to the narrow genetic base of most major crop plants has attracted considerable interest in genetic variation of domesticated species. More than 90% of the human food supply derives from a handful of grasses (wheat, rice, corn and oats), nightshades (tomato and potato), mammals (cattle, sheep and pigs), and birds (chickens and ducks) (Woodruff and Gall 1992). Their narrow genetic base is a major cause of disease and pest epidemics, and the result is a boom-and-bust cycle of agricultural yields. In that sense, the most important contribution from genetics to agricultural productivity comes from the location and use of genes for resistance to crop pests and pathogens. Disease-resistant crop varieties are currently grown on 75% of all USA croplands (Oldfield 1984).

The value of genetic diversity in this case lies in the fact that it provides the raw material for desirable genetic traits in crops. For example, mechanized harvesting of tomatoes was facilitated by a gene for a jointless fruit stalk. In nature this gene occurs only in a single population of a related species of tomato unique to the Galapagos Islands. The introduction of mechanized harvesting has meant a multi-million dollar saving for the tomato industry. The sugarcane industry had been on the brink of complete collapse on several occasions because of the *mosaic virus*, until the problem was solved by introducing resistance to it from wild relatives (*Saccharum spontaneum*). Wild coffee has been found which is resistant to the *rust* that has already devastated former coffee producing regions such as Sri Lanka, India, Java, the Philippines, etc., and wild sources of cacao have saved the industry from devastating *witches broom* (Oldfield 1984). In order to improve livestock populations, genetic resources have been used for obtaining traits that exhibit greater productivity, better resistance to pests, or specific adaptations to harsh environments. Furthermore, a multitude of species of plants, fungi, animals and microbes produce pharmacologically active substances such as alkaloids and glycosides used in Western medicine, and they cannot be considered apart from the genes and the organisms responsible for their production.

The value of genetic resources, like the value of other resources, is a function of both human preferences and technology. Recent changes in biotechnology are analysed elsewhere in this Assessment. It is clear, however, that these changes have altered both the direct usefulness (and so use value) of genetic resources, and the potential indirect consequences (externalities) of their use. For example, biotechnology makes gene transfer possible both within species and between unrelated species, increasing the utilization potential of genetic resources and hence their

value. Biotechnology, in the form of bioassays, has reduced the time and cost of screening for pharmaceutical and other uses, increasing the value of the underlying genetic resources. On the other hand, anything that raises the value of plant material may increase collection pressures, possibly leading in poorly controlled areas to over-exploitation and species loss. The indirect effects of biotechnology can be divided into secondary effects, those caused by the initial adjustments, and tertiary effects, encompassing subsequent adjustments. As a hypothetical example, biotechnology that replaced a broad spectrum synthetic pesticide with a more specific and less costly biopesticide would be expected to foster greater biodiversity of animal life in the area. This would be the secondary effect. However, as a consequence of lower costs, farmers might increase the area farmed, potentially degrading regional biodiversity, or alternatively they might reduce the land area farmed, with beneficial effects on biodiversity. These would be tertiary effects. Another example of a tertiary effect of biotechnology involves the production of pharmaceuticals. Better medicines have led to population increase which is linked with environmental degradation and biodiversity loss. However, because of their speculative nature, or because specific connections are unclear, tertiary effects receive limited attention.

There is at present very limited field experience with the products of biotechnology. In terms of the definition used in this Assessment, very few species altered by biotechnology are currently in commercial use. Consequently most indirect impacts of biotechnology applications cannot be analysed directly but rather must be assessed from related past experiences. Of these, the Green Revolution is perhaps the most relevant. Owing to the nature of the data, what can be projected most clearly of change is its direction, less clearly its magnitude. Productivity increases attributed to the Green Revolution have resulted in the same amount of food, feed and fibre being produced in the 1990s on about 40% less land than would have been required using 1960s technology. It is possible that biotechnology will have similar effects, although the reality will not be known for many years. Improvements in the feed conversion of animals (including fish) will reduce the land requirements to support the production of meat, milk and eggs. General outcomes, consistent with all types of productivity increase, include using less but better quality land, and reduced pressure for cultivating new land.

While this implies that the genetic resources embedded in the Green Revolution crops have direct value, it is not as clear what it implies for the value of the genetic resources in the supplanted crops. Traditional varieties are the result of millennia of selection by farmers, and are a major source of genetic diversity in agriculture and of genetic resources for plant breeding. Much use of such landraces ended with

Table 12.5-3: Examples of the productivity contributions of wild relatives of crops.

Crop	Found in	Effect on production
Wheat	Turkey	Genetic resistance to disease; valued at US\$50 million per year
Rice	India	Wild strain proved resistant to grassy stunt virus
Barley	Ethiopia	Protects California's US\$160 million per year crop from yellow dwarf virus
Hops	N. Europe	Added US\$15 million to British brewing industry in 1981 by improving bitterness
Beans	Mexico	Genes from the wild Mexican bean used to improve resistance to the Mexican bean weevil which destroys as much as 25% of stored beans in Africa and 15% in South America
Grapes	Texas	Texas rootstock used to revitalise the European wine industry in the 1860s after a louse infection

Source: see references in WCMC (1992).

the Green Revolution, when so-called improved varieties replaced the local varieties. For example, whereas Philippine farmers at one time used hundreds or even thousands of rice varieties, two varieties accounted for 90% of the area planted in one recent year (National Research Council 1993b, Ch. 1; Friis-Hansen 1994). Further improvements in varieties as a result of biotechnology are feared to displace yet more traditional varieties, exacerbating the loss of biodiversity and increasing the vulnerability of genetically uniform crops. The extent of this possible problem and appropriate management solutions are not clear.

The aggregate direct use value of biological resources and genetic material as ‘raw materials’ in agriculture can be approximated by the potential returns on investments in research and development of biotechnologies that may generate animal and crop breeds of potential value. The returns on this investment can be extremely high in some cases. For example, US public and private expenditure on corn breeding research in 1984 totalled US\$100 million and earned an estimated return of \$190 million. Studies that have estimated directly the contribution of genetic improvements to crop production also suggest that this value is substantial. For example, in the 1980s in the United States, the value of increased productivity of all crops from introducing new cultivars amounted to around \$1.0 billion per year. In Asia, the contribution of improved rice and wheat varieties through the Green Revolution was estimated to be \$1.5 and \$2.0 billion per year, respectively

(see WCMC (1992) for references to these studies and further discussions). Although many of these improvements have occurred through research and development finds from the existing genetic stock, in some notable cases this stock has had to be augmented by new ‘finds’ appropriated from wild relatives of existing crops – often to improve disease and pest resistance (see Table 12.5-3).

The appropriation of new genetic material and biological resources from the wild is also important in a number of other economic activities. For example, pharmaceutical companies are becoming increasingly interested in the potential biochemical properties of tropical species and varieties for developing new drugs. Based on data from Costa Rica, Aylward (1993) estimates that the net private returns to pharmaceutical prospecting of biological resources is around \$4.8 million per new drug developed. Over 50% of these royalty returns could realistically be allocated to biodiversity protection in Costa Rica. Such royalty arrangements may become more common as the value-added contribution of biological resources as new sources of genetic material in pharmaceutical development and other commercial products receives more attention.

An increasing number of examples illustrate that the productivity of ‘integrated’ domesticated and natural systems may be an improvement over monocultures. In southern Chile, for example, a combined aquaculture system based on seaweed, mussels and salmon production in coastal waters not only reduces resource use, waste problems and other environmental impacts, but if

effectively managed, will also transform excess nutrients from domestic sources into biomass and marketable products. The long-term productivity of the integrated system is an improvement over the unsustainable cage farming of salmon in monocultures (Folke and Kautsky 1992). Similarly, Lugo *et al.* (1993) demonstrate that forest plantations in Puerto Rico can be developed on converted old-growth forest land with a minimal loss of biological diversity. The resulting plantation forest could be exploited fully for both commercial timber and non-wood products.

It should be emphasized that the change in resource values as a result of biotechnology has important distributional implications. Unlike the Green Revolution's plant science, modern biotechnology is not available to those who cannot pay for it, i.e. most developing countries. It is in any case not currently well adapted to the problems of, for example, developing country agriculture. Overall spending on biotechnology research for the South is at least an order of magnitude lower than for the North. All this is despite the fact that the genetic capital which services much of the biotechnology industry leaves developing countries often free of charge (failure to protect intellectual property rights), only to return in the form of expensive new seeds, drugs and other patented items. The Convention on Biodiversity, signed at Rio de Janeiro in 1992, recognizes the validity of the unfair treatment complaints voiced by developing countries and stipulates that such countries should receive compensation for the export of their germplasm. This would go some way towards allowing developing countries to appropriate some or all of the contribution of their sovereign genetic material to global values.

Individual countries may also face difficulties, because although particular ecosystems are located within their sovereign boundaries the functions and services that flow from these ecosystems extend out beyond such boundaries. Examples include the support of mangroves for marine fisheries, the regional and global climatic influence of forest systems and the protection and water supply functions of major watershed systems. Ecological functions and services are therefore non-exclusive and contestable and thus have characteristics of common pool resources. Much will depend here on whether individual countries can directly capture a significant proportion of the function/service flow on their own territory and how important such instrumental values are to the local/regional/national economy. If biodiversity conservation loses out to national development activities then ecosystem function/service loss avoidance is possible only via compensation from developed to developing countries (Brown *et al.* 1993).

One way this might be done is via debt-for-nature-swaps. The swap works in the following way. An interested conservation agency buys up some of the developing country's international debt ('secondary' debt) on the

world's money markets. The debt is often priced at less than its face value because there is a risk that the indebted country will not pay the debt back. The conservation agency then promises to dispose of the debt in return for a promise from the indebted country that it will look after a conservation area, e.g. as a national park or a sustainably managed timber resource. Value appropriation mechanisms such as actual debt-for-nature swaps also provide an opportunity to find an approximate estimate of non-use values (existence value). By looking at what the conservation agency actually pays and the biodiversity areas conserved, a very rough approximation of the 'per hectare' value can be derived. On this basis global existence value for tropical forests would be in the order of US\$5 per hectare (Pearce and Moran 1994). There have been a number of debt-for-nature swaps so far, ranging from Bolivia to the Philippines and Zambia (Pearce and Warford 1993). Other value appropriation mechanisms are analysed in Chapter 12.6.

12.5.3 The value of species

In the late 1980s there was a dispute about the role of trade bans in the conservation of biodiversity. Most prominent amongst the trade bans being canvassed by the proponents of conservation was the ban on the ivory trade. Poaching was widespread and elephant populations in Africa were plummeting as a consequence. Some believed that the most effective way to save the elephant was to ban trade. To this end, some conservationists felt that it would be useful in the debate to have an estimate of the economic value of viewing elephants. The viewing value, to be sure, is only one component of the non-consumptive use value of preserving African elephants, but it is a start. A survey was designed to estimate the viewing value of elephants by tourists on safari in Kenya in 1988 (Brown and Henry 1993). The payment vehicle adopted was a lump sum increase in the respondent's safari cost of US\$100.⁷ A small sample size of 52 did not permit variation in the dollar amount across respondents. Those surveyed were also asked the maximum willingness to pay, in an open-ended question format. Sixty five per cent of the sample responded affirmatively to the dichotomous choice question. The average of the responses

⁷ The exact form of question and the open-ended version are:

Suppose that the current population of elephants can be maintained if additional foot, vehicle and aerial patrols are operated on a sustained and regular basis in the parks. If these patrols can be supported by a special 100 dollar annual permit (or included in each visitor's safari costs), are you willing to support this permit fee?

NO, I am not willing to pay \$100 for this permit.

YES, I am willing to pay \$100 for this permit.

I am willing to pay a maximum of _____ for this permit.

(Express this in U.S. dollars or specify in one of the currency equivalents in the table below).

Box 12.5-2: The Northern Spotted Owl.

In this study, respondents were offered a menu of five policies. Associated with each policy were three attributes: the number of acres of ancient forest protected, the number of Northern spotted owl pairs preserved and their probability of survival (or extinction); and the cost of implementing the policy (an extract from the survey appears below). Survey respondents, paid for their time, had read the subject matter and responded to questions about biodiversity, the ancient forest and Northern spotted owls before confronting the contingent ranking problem.

Survey results from just over 100 respondents were analysed using a conditional logit model (McFadden 1973, 1983; Maddala 1983) which is the standard method used by natural scientists for studying dose–response phenomena. From the parameters estimated in the analysis, it was possible to estimate that each household in the Pacific Northwest was willing to pay a lump sum of at least \$12.50 for improving the Northern spotted owl’s probability of survival by 1%, from 85 to 86%, for example. They were willing to pay a lump sum amount of at least \$50 for a one million acre improvement in ancient forests preserved. These estimates are not additively separate because providing an acre of habitat is valuable in its own right and further contributes to the survival of the owl.

Extract from the Northern Spotted Owl CV Survey

CHOOSING YOUR PREFERRED PRESERVATION PROGRAM

There is a multitude of other options possible for protecting the northern spotted owl and the ancient forest. For now though, assume that the government must select one of the preservation options. Even if none of the options are very attractive, one must be chosen. Note that everyone across the country will pay roughly the same amount for northern spotted owl and Pacific Northwest Ancient Forest preservation once an option is selected. On the next page please choose the cost of the one option that you would want the federal government to adopt. In making your choice, be sure to consider (a) how well the problem is solved by the option compared to the other options, and (b) how much the option costs your household.

Q28. Please select the option and the amount of money your household consequently would be willing to pay to protect the northern spotted owl and the Pacific Northwest Ancient Forest. (Circle the number of the *single* best answer.)

1. **\$1 per year for ten years** to manage the spotted owl.
 - Protect 1.5 million acres (21%) of ancient forest habitat.
 - Protect 450 northern spotted owl pairs (13%).
 - The northern spotted owl would have a 2% chance of surviving in the wild for the next 150 years (a 98% chance of becoming extinct).
2. **\$32 per year for ten years** to preserve some additional ancient forests.
 - Protect 2.1 million acres (30%) of ancient forest habitat.
 - Protect 1,000 northern spotted owl pairs (29%).
 - The northern spotted owl would have a 5% chance of surviving in the wild for the next 150 years (a 95% chance of becoming extinct).
3. **\$68 per year for ten years** to preserve half of the remaining ancient forests.
 - Protect 3.4 million acres (49%) of ancient forest habitat.
 - Protect 1,600 northern spotted owl pairs (46%).
 - The northern spotted owl would have a 72% chance of surviving in the wild for the next 150 years (a 28% chance of becoming extinct).

Box 12.5-2 cont.

4. **\$107 per year for ten years** to preserve most of the remaining ancient forests.

- Protect 5.2 million acres (77%) of ancient forest habitat.
- Protect 1,900 northern spotted owl pairs (54%).
- The northern spotted owl would have a 81% chance of surviving in the wild for the next 150 years (a 19% chance of becoming extinct).

5. **\$148 per year for ten years** to preserve almost all of the remaining ancient forests.

- Protect 7 million acres (100%) of ancient forest habitat.
- Protect 2,400 northern spotted owl pairs (69%).
- The northern spotted owl would have a 90% chance of surviving in the wild for the next 150 years (a 10% chance of becoming extinct).

If the estimated willingness to pay per household to preserve biodiversity is known, it can be scaled up by the number of households to obtain a total willingness to pay for biodiversity. How many households are there? More to the point, what is the extent of the market for this particular form of preservation of biodiversity? Respondents in the Northwest, specifically in the Puget Sound region of Washington, were the source of the estimated values above. There is very little research available regarding the spatial uniformity of non-use values for specific natural resources in general and species in particular.

To learn more about the value gradient with distance, the same survey was administered to more than 100 respondents in Colorado, about 1000 miles distant (Brown *et al.* 1994, unpublished). Interestingly, perhaps provocatively for sure, Colorado residents do not appear to value the ancient forest and the spotted owl in the Pacific Northwest, apart from maintaining the status quo. They would rather spend money to preserve biodiversity closer to home.

It would be instructive to compare the estimated total economic benefits and total economic costs of preserving the owl and the ancient forest at different levels of preservation. However, present uncertainty over the spatial variability of household values make this effort fairly speculative. Comparing the actual policy choice and alternative options with the optimal level determined by economic criteria is precluded until better estimates are available.

to the open-ended question was \$89 and the median value was \$100. Converting the sample values to the adult safari population yielded values of \$22–\$30 million per year depending on the choice of median or mean value and size of population on safari.⁸

While there can be debate about the precise meaning of biodiversity, no one would cavil about including endangered or threatened species such as the Northern Spotted Owl in the Pacific Northwest in the definition. Few would want to exclude the ancient forest in the same region as an important ingredient of its biodiversity. That is fortunate because there is a study by Brown *et al.* (1994) which values the Northern spotted owl and its ancient forest habitat (see Box 12.5-2). It is a rare application of the contingent ranking technique to the area of biodiversity.

The determination of existence value from the revealed preferences of individuals or groups in expenditures on conservation is limited to actual conservation issues which often concentrate on emblematic and charismatic species or

habitats. Yet the loss of environmental quality and biodiversity would lessen human welfare in other ways. These existence values are often elicited through contingent valuation survey techniques. The willingness to pay for the preservation of particular species, simply for the perceived welfare loss from the non-existence of these species, is shown in Table 12.5-4 for a number of endangered species. The surveys on which these estimates have been made often attempt to compare existence values with other use values, and find in general that existence value may be in the same order of magnitude as other values. In the case of

⁸ The viewing value of elephants was also estimated using an alternative method, the travel cost technique, which relies on differences in rates of participation associated with different travel costs to estimate economic value (consumer's surplus) over and above actual expenditures. Estimates of annual value using this technique varied between \$23 and \$27 million annually, depending on choice of total population taking a safari in 1988.

Table 12.5-4: Existence valuations for endangered species and prized habitats.

Country	Species or habitat	Expressed value (1990) (US\$ 1990 per person per year)
<i>Species</i>		
Norway	Brown bear, wolf and wolverine	15.0
USA	Bald eagle	19.1
	Striped shiner	5.0
	Grizzly bear	18.5
	Bighorn sheep	8.6
	Whooping Crane	6.5
	Wild Turkey	11.4
	Salmon	7.6
	Coyote	5.1
	Blue whale	9.3
	Bottlenose dolphin	7.0
	California sea otter	8.1
	Northern elephant seal	8.1
	Humpback whales	40–64
	Northern spotted owl (linked to old growth forest habitat)	21
	300 forest-related animal and plant species	7
<i>Habitat valuation</i>		
USA	Grand Canyon visibility	27.0
	Colorado wilderness	9.3–21.2
Australia	Nadgee Nature Reserve	28.1
	Kakadu Conservation Zone	40–93
UK	Sites of Special Scientific Interest ¹	40
	Lowland wetland bog	300
Norway	Conservation of rivers	59–107
	Preservation of coniferous forests	90–140
Sweden	Recreational and virgin forest areas	3–4
	All natural forests in Sweden	5–8

Source: Based on Samples *et al.* (1986), Boyle & Bishop (1987), Bowker & Stoll (1988), Stevens *et al.* (1991), Brown *et al.* (1993), Navrud (1992, 1993), and Directorate for Nature Management (1992).

preservation of endangered species, the studies by Samples *et al.* (1986) hypothesize that the expressed valuation is largely non-use existence value when respondents are informed of the endangered status of the species.

In the conservation of biodiversity there are inevitably trade-offs with other economic activities, yet existence and option values can often alone be of the same order of magnitudes as these competing uses. An example of such a study is the willingness to pay for preservation of a lowland bog area in the north of Scotland under threat from

commercial monoculture afforestation (Hanley and Craig 1991). The willingness to pay for preservation benefits of US\$300 per hectare, implicitly represents the discounted future stream of both use and non-use benefits.

If existence values are of the same order of magnitude as other indirect and non-consumptive use values, then evidence of these values indicates the scale of existence values. For charismatic species such as elephants, for example, the value elicited in contingent valuation surveys for their preservation partially represents non-consumptive

viewing values and future options to this, but also partially represents pure existence value (Brown and Henry 1993). In a contingent valuation of game viewing of elephants in Kenya, Brown and Henry (1993) elicit willingness to pay for maintenance of elephant populations using a hypothetical park entrance fee. Their results show that visitors gain approximately \$25–\$30 million per year in consumer surplus (value over what they actually pay) for viewing elephants, a proportion of which is likely to be existence value. On wider habitat protection, Moran (1994) shows that the consumer surplus attached to non-consumptive use of Kenya's protected areas by foreign visitors (as a subset of all users) is presently approximately \$540 million. As with the preservation of Scottish wetlands study, conservation of these areas therefore represents a sustainable utilization of resources, as these consumer surplus estimates are greater than estimated opportunity costs of preservation (i.e. other alternative economic activities) (Moran 1994). However, this is only a relevant policy measure if mechanisms are devised to capture existence and other non-use values.

Not all aspects of the natural world or all species are perceived in anthropocentric terms as having positive intrinsic value. In other words, observational and empirical evidence suggests negative existence values for some species. For example, festivals and cultural events in the USA focus on making undesirable native species locally extinct. These include rattlesnake 'round-ups' in Texas and elsewhere, and the shooting of prairie dogs in Colorado. Although the justification for these events often stresses the economic and supposed ecological 'benefits', they also are justified in terms of potential human welfare (an indirect use and option 'value') and by a general aversion to the species (Weir 1992).

Surveys of the motivational bases of hostile attitudes to invertebrates find that invertebrates are associated with disease and agricultural damage (an indirect use or option valuation again), but also that hostility is promoted by perceptions of invertebrates having no identity or consciousness (Kellert 1993). This is strong anthropocentrism; in other words invertebrate species do not have the same intrinsic rights as, say, mammals, and the 'desire for sterile home environments and modern theories of disease transmission may exacerbate human fears, particularly in highly urbanized, industrial societies' (Kellert 1993: p. 852). The policy implications of this aversion and the negative existence values of species would seem to be to provide information on their ecological importance within whole ecosystems and therefore the importance (primary value) of a whole system evolving in a 'healthy' condition.

12.5.4 Estimates of the value of Parks and protected areas

An increasing number of studies in recent years have applied various valuation methods to value Parks and other protected areas. Here we select a small sample of these

studies to illustrate the use of different valuation methods in valuing different forest products, services and functions of tropical forest habitat and to provide a sense of the range of values that are obtained compared with traditional forest values.

Tobias and Mendelsohn (1991) have estimated the value of ecotourism in the Monteverde Cloud Reserve in Costa Rica using the travel cost method. This study avoided the problem of meanderers by studying only Costa Rican visitors, for whom the sole purpose of the journey was to visit the site in question, the Monteverde Cloud Forest Biological Reserve. Costa Rica's 71 Cantons were used as observations, and visitation rates and the cost of travel were calculated for each one. Demand for the site was estimated as a function of price, population density and illiteracy rate, yielding the expected coefficients, negative, positive and negative, respectively. The average consumer surplus for the sample was estimated at US\$35, which, extrapolated over the entire visitor population and using a real rate of interest of 4%, yields a net present value for recreational use of the forest of \$1250 per hectare. The World Bank estimates that activities related to tourism world-wide approaches \$2 trillion annually. Ecotourism is emerging as one of the fastest growing components of this industry, with as many as 235 million individuals participating in 1988, resulting in economic activity estimated at \$233 billion. More than half of this ecotourism was related to animals (Filion *et al.* 1994).

This is probably an underestimate since foreign consumer surplus is assigned the domestic value; in fact it is almost certainly higher, and growth in visitation rates is not accounted for. Even so, since the preservation cost of Costa Rican rain forest is between \$30 and \$100 per hectare, this measure of value alone would appear to provide a clear justification for expansion of the conservation programme. They obtained a net present value of ecotourism benefits (consumer surplus) for both domestic and foreign visitors totalling US\$8 million for the 10 000 ha reserve or \$1250 per hectare. This compares very favourably with a \$30–\$100 per hectare price of agricultural land in surrounding areas. Therefore, conversion of forest land to agriculture in the area would result in a social loss of \$1000 per hectre, while expansion of the reserve would generate a substantial social gain. Yet, if the ecotourism value of the forest is not internalized to local landowners, expansion of the parks is uneconomic in private terms.

Munasinghe (1993) presents the preliminary results from a World Bank study that assesses the costs and benefits across different socioeconomic groups resulting from the creation of Mantadia National Park in Madagascar (see Kramer *et al.* (1992) and Kramer (1993) for more details on this study). Like many other tropical developing countries, Madagascar is one of the world's most ecologically rich

countries, but is also one of the world’s most economically poor countries. In response to the severe threat of forest degradation and biodiversity loss, Madagascar is considering creating additional parks and national reserves. To offset the opportunity costs imposed on local people by park creation and to increase the likelihood of forest protection, nature tourism and buffer zone activities have been included in some park projects.

Two of the more important and more difficult to measure economic impacts of national park creation are the costs incurred by local villagers and the benefits received by foreign tourists. The opportunity cost approach, travel cost method and contingent valuation approach were used to assess these values in the new Mantadia National Park. To estimate the proportion of travel expenditure which should be attached to the site in question, a series of questions was prepared regarding costs, itinerary, willingness to pay for the site, as well as economic and sociodemographic characteristics. The preliminary results are summarised in Table 12.5-5.

The *opportunity costs of park creation* incurred by local villagers include the forgone benefits they previously derived from the forest, such as fuelwood, fish, animals, grasses, and fertile land for shifting agriculture. A survey of 351 households in 17 villages within a 7.5 km radius of the park boundary was conducted. The survey indicated that most households engage in shifting cultivation and rely on forest clearance for their land. In addition, they obtain significant quantities of fuelwood, crayfish, crab, tenrec and frog from the forest. Using market prices in conjunction with estimates of the quantity of products extracted from the forest, the opportunity costs to villagers of losing access to Mantadia National Park were estimated to be US\$91 per household/year on average, or \$556 010 in present value terms for all households. This was considered an upper estimate of the benefits derived by local villagers

from the park, as it does not take into account access to alternative forest resources outside the park.

In addition, a *contingent valuation method* (CVM) survey established that on average a compensation of 108 kg of rice will make the villagers as well off with the park as without the park. For all households covered by the survey, this implies a necessary one-time compensation of approximately \$673 078 for all use and non-use benefits that the villagers derive from the park. A *travel cost* study was also administered to tourists visiting the nearby small Perinet Forest Reserve, adjacent to Mantadia National Park. The CVM and travel cost studies of tourists yielded estimates of the net present value of tourism benefits associated with the park amounting to \$796 870 and \$2.16 million, respectively.

Dixon and Sherman (1990) have estimated the value of biodiversity of the Khao Yai Park in Thailand at \$4.8 million per year and its ecotourism value in the range of \$0.4–\$1.0 million per year. These values compare favourably with the almost \$7 million a year loss of income to villagers from traditional users forgone due to the park. On the benefit side, the watershed and carbon sequestration value of the forest were not estimated, nor were the non-use values. On the opportunity cost side, the value of forgone timber harvesting was similarly left undetermined.

Barbier *et al.* (1994) note several important lessons for economic valuation of the costs and benefits of a forest land-use option that can be drawn from the Mantadia study. First, valuation techniques need to be adapted to local situations – in this case rice was used as the basis for measuring the value of forest benefits forgone by villagers through the establishment of the protected area. Second, careful application of valuation techniques in relevant decision-making situations can provide useful indications of which forest values are being affected by the choice of land use. However, it is important to keep in mind what is

Table 12.5-5: Valuation of biophysical reserves in Madagascar.

Items valued	Valuation technique	Aggregated net present value (20 years and 10% DR)
1. Direct use benefits of forest by local villagers – agriculture, fuelwood, crayfish, crab, tenrec, frog	Opportunity cost (production function approach)	US\$566 070
2. Net benefit of forest for local villagers – including use and non-use costs and benefits	Contingent valuation	US\$673 078
3. Direct use benefits of tourists – tourism benefits only	Travel cost	US\$796 870
4. Net benefit of park creation for tourists – may include tourism and other perceived benefits and costs of park creation, e.g. lemur conservation	Contingent valuation	US\$2 160 000

Source: based on Munasinghe (1993) and Kramer (1993).

actually being measured by the valuation technique, e.g. direct use benefits, net benefits including use and non-use benefits, etc., and the reliability of the data and methodologies in assessing these different benefits. Even more important, although this study was concerned with the establishment of a protected area to conserve biological diversity, it did not assess the role of the biodiversity of the forest in maintaining ecosystem functioning and resilience. Consequently, it could not determine whether loss in biodiversity through direct exploitation of the forest by the villagers would have affected their ability to sustain these uses over time. We now consider the results of studies that have widened the range of effects to be valued.

12.5.5 Concluding remarks

Many domesticated **biological resources** are traded on markets, and their direct use values (such as crops, livestock and timber) are reflected in their market prices. The production of such commodities, however, depends on a range of non marketed environmental inputs. This chapter has reported current estimates of the value of these non-marketed inputs. Several general observations can be made about these estimates.

- Nearly all modern crop varieties and some highly productive livestock strains contain genetic material incorporated through plant breeding, from related wild or weedy species, or from more primitive genetic stocks. The direct use value of **genetic diversity** lies in the fact that it provides the raw material for desirable genetic traits in crops or livestock.
- **Biotechnology** has increased the utilization potential of genetic resources, and hence their direct use value, by making gene transfer possible both within species and between unrelated species. **Bioassays** have reduced the time and cost of screening for pharmaceutical and other uses, also increasing the value of the underlying genetic resources.
- The aggregate direct use value of genetic material, as 'raw materials' in agriculture can be approximated by the potential return on investments in research and development of biotechnologies that generate animal and crop breeds of potential value. The returns on this investment can be extremely high in some cases.
- Amongst **wild biological resources**, the direct use value can be highly significant, even in developing countries. In particular, charismatic species such as elephants have high **non-consumptive, option, and existence** values which may be partly captured through park fees.
- The local benefits of biodiversity conservation are generally exceeded by the local opportunity costs

(forgone development benefits). The opportunity costs of park creation to local villagers include the forgone benefits they previously derived from the forest, such as fuelwood, fish, animals, grasses, and fertile land for shifting agriculture. This discourages conservation. Conservation requires an incentive structure that raises the local benefits. For some ecosystems, where global values dominate local values, international transfers are needed to correct market and policy failures.

12.6 The valuation of ecosystem functions: empirical results

12.6.1 The indirect value of biological resources

Indirect use values comprise mainly the environmental functions of natural areas – ecological functions such as nutrient cycling, protection functions such as ground cover for key watersheds, waste assimilation functions such as the retention or de-toxification of pollution, and wider functions such as microclimatic stabilization and carbon storage. These environmental functions all indirectly support economic activity and human welfare, and are generally the *regulatory functions* performed by ecosystems (see Table 12.6-1). If the role of individual species in mediating such regulatory functions is understood, then it is, in principle, possible to derive the indirect use value of such species. For example, elephants are known to have an essential ecological role in African savannahs and forests through diversifying ecosystems, dispersing seeds, reducing bushlands, expanding grasslands and reducing tsetse fly, all of which may be of value to livestock grazing (Western 1989).

Indeed, the relationship between individual organisms and ecosystem functioning is key to the concept of indirect use value. Each ecosystem is composed of a number of physical, biological and chemical components such as soil, water, plant and animal species and nutrients. Processes among and within these components result in specific types of *ecosystem function* or property such as nutrient cycling, biological productivity, hydrology and sedimentation. All such ecological functions are important in maintaining the overall performance and integrity of the ecosystem, in particular its fundamental role in supporting and sustaining the various living organisms dependent on it.

These interactions, or *life-support functions*, in turn generate many ecological resources and services that are of fundamental value as they sustain human societies and existence (see Table 12.6-1). As indicated in the previous Chapter, the kind of ecological resources and services derived from production, carrier and information functions generate economic benefits in the form of direct use values. The regulation (or regulatory) functions tend to generate

Table 12.6-1: Ecosystem functions and their uses.

Regulation functions	Production functions	Carrier functions	Information functions
Providing support for economic activity and human welfare through:	Providing basic resources, such as:	Providing space and a suitable substrate inter alia for:	Providing aesthetic, cultural and scientific benefits through:
– protection against harmful cosmic influences	– oxygen	– habitation	– aesthetic information
– climate regulation	– food, drinking water and nutrition	– agriculture, forestry, fishery, aquaculture	– spiritual and religious information
– watershed protection and catchment	– water for industry, households, etc.	– industry	– cultural and artistic inspiration
– erosion prevention and soil protection	– clothing and fabrics	– engineering projects such as dams and roads	– educational and scientific information

values more indirectly, through their support and protection of various economic activities located outside the ecosystem but nevertheless dependent on its proper ecological functioning.

Table 12.6-2 reports the results of a few studies of indirect use values from various regions and ecosystems. Once again, these are in the nature of snapshots, but the method could be used to generate time series that would enable policy-makers to identify trends.

12.6.2 Estimates of the use value of forests

Tropical moist forests harbour between two-thirds and three-quarters of the world’s species. However, we emphasize that the remarks made about tropical forests

apply, *mutatis mutandis*, to other habitats. The particular problem posed by the conversion of tropical forests is that while human-made plantations maintain rainfall regimes and cycle carbon at rates similar to those of indigenous forests, genetic resources are eliminated when indigenous forest is converted to plantations. Conservation of genetic resources should be evaluated along with other goods and services provided by forests, and should form an integral part of land use and management. This is not to say that all forests should be preserved. The aim of conservation should be to optimize the provision of ecological and other services and this does not necessarily imply the preservation of the existing resource in all its facets.

Table 12.6-2: Estimates of the indirect use value of ecological functions.

Resource/function	Estimated value (US\$)	Source
Cameroon		
Watershed protection of fisheries	\$54/ha	Ruitenbeek (1989)
Control of flooding by forests	\$23/ha	
Soil fertility maintenance by forests	\$8/ha	
Philippines		
Watershed protection of marine tourism	\$13.9–19.2 million	Hodgson and Dixon (1988)
Watershed protection of fisheries	\$6.2–8.1 million	
USA		
Water-yield augmentation of managed forests	\$232–388/acre	Bowes and Krutilla (1989)
Brazil		
Carbon storage by forests	\$1300/ha/year	Pearce (1990)
Indonesia		
Support by mangroves of agriculture, fishing and cottage industries	\$536 million	Ruitenbeek (1992)
Sweden		
Nitrogen reduction by restored wetlands	\$18.7/kg N-reduction	Gren <i>et al.</i> (1994)

Tropical forests provide a diverse range of functions and services, including sustainable timber production, non-timber forest products, soil conservation and watershed protection, habitat for biodiversity, homeland for indigenous people, recreational services, amelioration of microclimate, and carbon fixation and sequestration. While all of these functions and services have positive economic value that contributes to human well-being, they are rarely taken into account when land-use and forest management decisions are made. Certain forest values, such as timber production and the potential use of forest land for agriculture, tend to dominate forestry decisions while indirect values, such as the forests' ecological functions, biodiversity and value to indigenous people, are routinely ignored for reasons that range from the difficulty of quantification and valuation to their public good aspects (market failure) to perverse incentives (policy failure). The most direct and tangible uses of forests (timber production and conversion to farmland) are either potentially threatening to the forests' existence or outright

incompatible with it, while the forests' ecological services, which go ignored, are consistent with (in fact, requisite for) the forests' existence in a fairly pristine state.

The total economic value of tropical forests as habitats consists of the sum of their use and non-use values with due consideration of any trade-offs or mutually exclusive uses or functions. The use values may be direct or indirect, current or future (expected or optional). Direct use values include non-timber forest products, medicinal plants, plant genetics, hunting and fishing, recreation and tourism, and education and human habitat, because all of these products and services involve direct use of the forest. Indirect use values include soil conservation and soil productivity (through nutrient cycling), watershed protection with derivative services of water supply and storage, flood control, etc., microclimatic effects and carbon sequestration. Unlike the direct use values, indirect use values do not require physical access to the habitats, but mere physical existence of the forest in good condition. A third category of use value is the option value – the

potential value of habitats for future (direct or indirect) use. It is an insurance premium that people may be willing to pay to ensure supply and opportunity to use in the future. Of course this value is positive only if demand is expected to exist in the future (certain) and supply is uncertain. In the case of habitats, this value is likely to be positive.

Traditionally, many of the indirect use values and non-use values of tropical forests have been ignored, partly because of the difficulty of estimating such values and the lack of mechanisms to incorporate them into decision-making, but most importantly because of the limited appreciation of the importance of the values to ecological sustainability and human welfare. Even direct uses, such as the production of non-timber forest products and the value of forests as human habitats, especially for indigenous people, have not played an important role in tropical forest use decisions. The labelling of non-timber products as minor forest products is a measure of the low significance attached to products and *a fortiori* to services other than timber.

We begin by considering the estimates of value derived from a comprehensive cost–benefit analysis (CBA) of the Korup Project in Cameroon. The Korup Project is an ongoing programme to promote conservation of the rain forest in Korup National Park in Southwest Province, Cameroon. As indicated in Table 12.6-3, the net benefits of the Korup protected area project in terms of sustained forest and subsistence use, tourism, genetic value, watershed protection, control of flooding and soil maintenance, all compare favourably with the opportunity costs of forestry and other development options, thus generating a substantial overall net benefit to Cameroon.

In addition, the analysis not only indicates the range of values that may need to be assessed in deciding whether it is worthwhile establishing protected areas for conservation but also illustrates the procedure for valuing alternative tropical forest land-use options. The CBA includes not only the direct operating and capital costs of the Project but also the *opportunity costs* of lost timber earnings from forgoing clear-cutting (lost stumpage value) and lost production from the six resettled villages (lost forest use). Against this must be weighed the benefits of the project in the form of sustained forest use beyond the year 2010 when the forest would otherwise have disappeared, replacement subsistence production of the resettled villagers, tourism, minimum expected genetic value of biological resources in terms of pharmaceuticals, chemicals, agricultural crop improvements, etc., and environmental functions – watershed protection of fisheries, control of flooding and soil fertility maintenance. Also included are ‘induced’ benefits, agricultural and forestry benefits of the project’s development initiatives in the buffer zone. The external trade credit shows a positive benefit to Cameroon of direct external funding of the project. ‘Uncaptured genetic value’

is a negative adjustment reflecting the fact that Cameroon will be able to capture only 10% of the genetic value through the licensing structures and institutions that it has in place, and ‘uncaptured watershed benefits’ indicates that some of the watershed protection benefits will flow to Nigeria and not Cameroon. Thus the analysis indicates that the Korup Project offers substantial net economic benefits as a land-use option at the project level and to Cameroon as a whole.

The analysis also reveals some of the pitfalls of economic valuation of non-market environmental values, particularly ecological functions (Aylward and Barbier 1992). The watershed protection functions of the Korup rain forest serve two important regulatory functions: flood control and maintenance of an onshore fishery. Ruitenbeck calculates the value of both functions through the damage

costs avoided approach. Using estimates for the share of local economic output likely to be lost by flooding and for the periodicity of major floods, Ruitenbeek concludes that the damage costs with full deforestation would be US\$1.58 million. Similarly, the value of maintaining the onshore fishery is estimated to be worth \$3.78 million. The latter figure is essentially the total value of the fishery downstream to Cameroon, which is eventually adjusted for the 'uncaptured' benefits of \$0.35 million to Nigerian fishermen.

However, the ecological assumptions behind the damage cost methodology used in valuing the flood control function are not clear and possibly incorrect. First, an implicit assumption in the analysis is that the fishery would be a total loss if the Korup Forest were removed. Valuable though the watershed protection function may be, it is unlikely to be so essential that the entire fishery would be eliminated by the loss of this function. In fact it is probable that the low rates of deforestation projected by the CBA scenario may have a proportionately smaller impact on the fishery than that implied by a more rapid rate. This points out that the rate of deforestation may be one factor determining the extent of the damage done to the fishery when the watershed protection function is fully destroyed.

In addition, the rationale for assuming that the damage function produces linearly increasing costs to fishery production as the absolute area deforested increases is also questionable. Ruitenbeek assumes that the damage costs he calculates for total deforestation are divisible by segments corresponding to the proportionate size of the area deforested each year. It may be that the amount of deforestation and concurrent degradation of the protection function causes little damage up to some threshold amount of degradation at which considerable damage is incurred. A final point of criticism derives from Pearce (1990), who cautions against assuming that deforestation itself leads to the loss of functions such as flood control or fishery maintenance. Instead it is the ensuing landuse that is all-important in determining the extent of damage to the protection function.⁹

In comparison, a cost-benefit analysis of fisheries and tourism versus logging activities in Bacuit Bay, Palawan, Philippines (see Table 12.6-4), indicates a more valid approach to valuing the downstream impacts of forest degradation and depletion (Hodgson and Dixon 1988). It also provides an excellent example of the economic value of conserving biological diversity – although in this case it is not the loss of forest biodiversity but the damage to coral diversity of downstream sedimentation that is one of the critical environmental costs of deforestation.

The authors trace the impact of sedimentation resulting from logging activities through to its impact on coral cover, coral diversity and fish production in the coastal area of Bacuit Bay, as well as the loss of marine tourism resulting from decline of the coral reef and increased sedimentation of the water. Thus the analysis is essentially a comparison of the alternative uses of the terrestrial and marine areas within the Bacuit Bay system. However, it can easily be reinterpreted as a study of the land-use options for the forested area lying within the drainage basin of Bacuit Bay. For example, Hodgson and Dixon essentially compare the option of continued logging in the drainage basin area of the bay with an alternative scenario where the downstream economic benefits of fisheries and tourism undertaken in the bay are protected from sediment pollution by a logging ban in the drainage basin.

The dependence of fish on both coral cover and diversity establishes a potential link between forest degradation, ensuing sedimentation of coastal waters, changes in coral diversity and fish biomass. Using regression analysis Hodgson and Dixon found that 100 million tonnes per km² of annual sediment deposition led to one coral species extinction per year. This extinction was in turn correlated with a decrease in fish biomass of 0.8%. The negative impact of 400 million tonnes per km² deposition per year on coral cover was calculated to cause a 2.4% decrease in fish biomass. Similarly, as marine tourism is dependent on pristine coral reefs and seas, the decline in coral cover and diversity as well as the increased sedimentation and turbidity in coastal waters is expected to affect tourism revenues drastically. Both these impacts indicate the damages to the watershed protection function provided by the forest that result from continued clear-cut logging in the drainage basin. As shown in Table 12.6-4, these damages are highly significant, and suggest that the option of banning logging in the drainage basin is the preferred option – even though timber revenues would be sacrificed.

Peters *et al.* (1989), using the productivity/earnings method, have estimated the value per hectare of Peruvian forest (at Mishane, RioNanay), under alternative uses. They obtain a net present value of US\$6300 per hectare for non-timber forest products (fruit and latex) harvesting, \$490 for sustainable timber production, \$1000 for timber clear cutting, \$3184 for plantation harvesting and \$2960 for cattle ranching. Clearly, for this particular forest the highest value use is the sustainable harvesting of non-timber forest products. Of course, to arrive at the total economic value of the forest, its indirect use values (ecological) and non-use values must also be included as they are consistent with sustainable non-timber product harvesting. It is not clear how representative their sample was or if timber was shadow-priced to account for underpricing.

Anderson (1987) has demonstrated that the valuation and inclusion of the environmental benefits in the appraisal of

⁹ Ruitenbeek (1992) has conducted an excellent analysis of different scenarios for wood chip exploitation of mangroves in Bintuni Bay, Irian Jaya, Indonesia that follows this approach. For further discussion and review see Chapter 12.3.

Table 12.6-4: Philippines – logging versus fishing and tourism in Palawan.

Base case	1986 US \$ '000, NPV of 10-year sum of gross revenues		
	Option 1	Option 2	Option 1 - 2

forestry projects can increase substantially the economic rate of return of forestry investments. Specifically in the case of Northern Nigeria, the author has demonstrated that taking only the wood benefits into account results in uneconomic rates of return (and negative NPV) for both shelterbelts and farm forestry projects. When the environmental benefits of these projects such as the increase in soil fertility, the reduction of soil erosion and non-wood products are included, both types of projects become economically viable with social rates of return between 13 and 22%.

Ecotourism benefits are a major component of the total economic value of protected tropical habitats. Mercer *et al.* (1994), using travel cost and contingent valuation methods, have estimated the nature tourism benefit associated with establishment of the 10 000 hectare Mantadia National Park in Madagascar already referred to in this chapter. Mantadia provides a habitat to many endemic species, including several species of lemur. The travel cost method was used to estimate changes in ecotourists, consumer surplus resulting from the creation of a new park, which will improve the quality of ecotourism to Madagascar, while considering competing ecotourism destinations. The study estimated that creation of the park will result in increases of consumer surplus in the range of US\$0.77–2.24 (in present value terms at 4% discount rate)

depending on the expected level of quality improvement, e.g. more trails, nature education centre, trained guides. The values quoted above are for quality improvements in the range of 50–100%. The contingent valuation study estimated the willingness of nature visitors to Madagascar to pay for inclusion of the new National Park in their visit to the country. The average willingness to pay was estimated at \$65 per household for a total discounted present value of \$6.34 million. The higher values obtained by the CVM were expected and can be explained partly by their inclusion of non-use values (especially existence value) in addition to the recreational use value. The TCM is also known to underestimate willingness to pay for environmental improvements and in this particular case the value of the travel time was not included in the CVM, resulting in further underestimation of the consumer surplus from the new park. On the other hand, the CVM is likely to have overestimated the use value of the new park because, unlike the TCM, it did not explicitly control for substitute sites (competing destinations).

The Mercer *et al.* study implies an ecotourism value of habitat in the range of US\$224–\$634 per hectare or an annual value of \$9–25/ha over a 25 year period. These figures compare favourably with the opportunity costs of the park obtained by Kramer *et al.* (1994). The authors estimate the opportunity costs of the establishment of the

park using two alternative methods: (a) the value of forgone uses of the forest to the villages around the park (forgone earnings/benefits method) based on household cash-flows, constructed from a socioeconomic survey, and (b) direct questioning of the villagers on their willingness to accept compensation for the lost access to and benefits from the forest to be declared a National Park. The benefits to the villagers from the forest, to be lost as a result of the creation of the park, include fuelwood, other forest products and shifting cultivation. The forgone benefits method gave an average figure of losses of \$91 per household per year, or an aggregate net present value for all affected households of \$566 000 (at 10% discount rate).

The contingent valuation asked villagers for their willingness to accept compensation in the form of rice in order to be as content after the creation of the park as before when they could use the forest for collection of fuelwood and various forest products and for shifting cultivation. The respondents were asked to consider various aspects of the forests, both positive (e.g. protection from flooding and soil erosion) and negative (e.g. wildlife as destroyer of crops) in expressing their willingness to accept. The average willingness to accept was thus estimated at \$108 worth of rice per year, per household, or an aggregate net present value of \$673 000 (at 10% discount).

Converting these values on a per hectare basis we obtain an opportunity cost of US\$57/ha and a willingness to accept (WTA) of \$67/ha which are only a fraction of the ecotourism value of the forest as estimated by the Mercer *et al.* study. Even if we use a 4% discount rate to capitalize the villagers' losses and WTA to make them strictly comparable to the ecotourism benefits, they are still between 22 and 75% of the ecotourism benefits. However, the establishment of the park will have other benefits such as carbon sequestration, as well as costs to establish it and protect it.

Estimation of the forest benefits to local populations is indispensable to biodiversity conservation for several reasons; (a) local benefits that are enhanced and sustained by the establishment of a protected habitat serve to complement the biodiversity and other related benefits, making the establishment of the protected area less costly and more beneficial; (b) local benefits that are incompatible with biodiversity conservation and would be foreclosed by it constitute part of the overall cost of conservation and must be deducted in establishing the net value of the protected habitat; (c) forgone local benefits due to the establishment of a protected area constitute the minimum level of compensation needed to ensure the co-operation of the local population (otherwise the conservation area will be either unfeasible or too costly to maintain). It is the minimum level of compensation, because the local population may assign a greater value to their access to the

forest than is revealed by the value of the products and services derived from it. Their willingness to accept compensation obtained through contingent valuation surveys represents more fully their valuation of the forest access.

For example, Campbell (1993) has estimated the value of woodland resources to a local population in Zimbabwe using (a) a mixture of replacement and production value methods and (b) contingent valuation. The first method valued fruits and other wild foods, fuelwood, construction materials from the forests, and crop and livestock production attributable to the woodlands, and arrived at an average value of US\$223–\$267 per household per year or \$53–68 per hectare per year. Contingent valuation of these products plus ecological, social, and health services of the woodlands produced a mean value per household of \$537, or \$96–\$153/ha/yr based on average woodland availability in the range of 3.5–5.6 ha per household. What is not known is whether the current uses of woodlands are sustainable: if they are not sustainable these values are overestimates of local benefits. Biodiversity and ecological functions may be diminished by excessive harvesting of fuelwood, fruits, construction materials and fodder. Creation of biodiversity reserves would enhance biodiversity values as well as other indirect values such as ecological functions and non-use values such as existence value but would reduce (or even eliminate) use values such as fuelwood collection, grazing and timber harvesting. Precise estimation of the trade-offs is necessary to determine the combination of uses that maximize the woodlands' global net present value and the necessary compensation (transfers) for lost local benefit.

Again, the above values are not comprehensive. For example, the local benefits need to include the value of subsistence hunting, estimated at US\$2.6 per hectare per year by Murindagomo (1988), as well as the value of nature tourism based on wildlife resources associated with the woodlands. On the global benefit side, the value of woodlands ought to include not only the value of biodiversity but also the value of stored carbon, estimated by Bojo (1993) to have a present value of \$200 per hectare (or \$20/ha/yr) using Nordhaus's (1991) rather conservative carbon reduction costs.

Brown and Pearce (1994) estimate the (net) carbon released from deforestation of secondary and primary tropical forests to be in the range of 100–200 tonnes per ha. At a 'central' value of US\$20 per tonne, for global-warming-related damage (Fankhauser 1995), deforestation of one hectare of natural forest results in global warming damage of \$2000–4000, even after allowing for carbon fixation by alternative land uses. These estimates suggest a present value of forest as carbon sequester in the range of \$2000–\$4000 per ha. Inclusion of this value among the forestry benefits is likely to make many reforestation and

forest conservation projects economically viable (even at market discount rates), that would otherwise be uneconomic. The key here is the development of mechanisms for the appropriation and the internalization of these global values to the forest owners or decision-makers.

Table 12.6-5 summarizes the values per hectare of tropical forest per year obtained by studies in various parts of the tropics. They are all partial rather than total economic values; they consist mainly of direct use values

and ignore indirect use and non-use values. Yet, in many cases these values are substantial and compare favourably with returns from alternative uses, except for the outright liquidation of the forest and conversion of the land to other uses. Even with regard to the latter the picture changes for most tropical forests if all direct and indirect use and non-use values are included in the valuation of tropical forests. Table 12.6-6 presents a hypothetical example of the order of magnitude expected if one were to include all mutually

Table 12.6-7: Evidence of existence value for biodiversity conservation in Mexico.

Type of Evidence	Organisation	Area Involved	Size (ha)	Amount of transaction (US \$)	WTP per hectare (US \$)

compatible use values in the valuation of one hectare of tropical forest. (While the individual values are obtained from valuation studies of actual sites, their aggregation into one value is illustrative only because the sites are not strictly comparable.)

12.6.3 The total value of forests

A first attempt to arrive at the total economic value of tropical forest habitats, inclusive of use and non-use values, is made by Castro (1994) drawing on value estimates by Constantino and Kishor (1993) and World Bank (1994). The author arrived at an average total economic value for the tropical wildlands of Costa Rica of US\$102–\$214 per hectare per year, or a net present value of \$1278–\$2871 per hectare (using a discount rate of 8%). Multiplying these values with Costa Rica's 1.3 million ha of the wildlands, they put the annual value of the country's wildlands in the range of \$133–\$278 million and their net present value in the range of \$1.7–\$3.7 billion, of which 34% accrues to Costa Rica and 66% to the global community.

A more recent valuation study (Kaosard *et al.* 1994) of the Khao Yai Park in Thailand combined travel cost and contingent valuation methods to estimate both the use and

non-use values of the park. It arrived at a total economic value of US\$80 million per year or \$400/ha. This value does not include the non-use value to non-residents of Thailand nor does it include carbon sequestration values. Yet it compares favourably with the average returns from agricultural land of \$250 per hectare. The average willingness of Thai users to pay to protect the Khao Yai park was \$32 per person per year and of non-users \$8 per person per year. If we assume the same existence values among users and non-users, a quarter of the user's willingness to pay of users was for non-use values. While no survey of foreign users and non-users was carried out, it cannot be assumed that their willingness to pay to protect the park is zero.

In a contingent valuation study of Pennsylvania citizens, Griffith (1991) found that the average non-user of tropical forests was willing to pay US\$28 to protect them. Since a non-user is defined as one who has never visited nor intends to visit tropical forests, this value can be interpreted as a purely existence value. As one would expect, the average Pennsylvania user of tropical forests was willing to pay a lot more, estimated at \$72, to protect the rain forests. Assuming again that users and non-users hold the same

existence values, as much as 40% of the user's willingness to pay is a non-use value. De Groot (1994) based on research in the Darien MP (Panama) and literature data arrived at a total economic value of tropical forests of US \$500 per ha per year for all quantifiable functions of this rain forest area.

The available developed country evidence (summarized above) suggests that non-users have typically indicated values in the range US\$5–\$64 per annum per person for wild species, while per annum WTP for scenic and wilderness areas range between \$3 and \$140. Existing studies provide indicative values where a full range of studies is not possible for every habitat type or for each endangered species. The wisdom of transferring benefit estimates from other similar sites continues to be the subject of scrutiny in valuation literature (Brookshire and Neill 1992). Most valuation studies relate to the US or other developed countries. The results are context and culture-specific and have a limited applicability across all countries.

Table 12.6-7 presents elements of revealed value for a sample of transactions related to natural area conservation for Mexico's forests. Mexico is species-rich: its tropical moist forests contain 5000 vascular plant species as a lower bound estimate (Toledo *et al.* 1992), with all habitats containing 20 000 to 30 000 plant species (WCMC 1992; Bye 1993). Reported elements of existence value include contributions to conservation organizations and programmes, a tourism survey, and debt for nature swaps. On the basis of this evidence, indicative values would appear to be in the range US\$0.03–\$10.4 per hectare. Mexico's protected areas cover approximately 5.8 million hectares and range from tropical evergreen rain forest to arid desert areas. This range of existence values relates to only some of the range of Mexican habitats, highlighting the issue that existence value is context-specific and rises with increasing threat to the habitat.

As reported by Pearce and Moran (1994), the range of implicit values is from US\$0.01 to just over \$4 per hectare globally. The idea of valuing the biodiversity conserved through debt for nature transactions is that the payment made reflects some kind of willingness to pay on the part of the conservation body purchasing the debt. Different debt for nature transactions result in different implicit valuations since the nature of the 'good' being bought varies with the quality of the area protected and the land management strategies involved.

12.6.4 Valuation and policy

If biological resources are to be effectively and sustainably managed, the consensus amongst economists is that there is an urgent need to value the totality of goods and services (including non-use values) provided by ecosystems. Existing estimates of the value of ecological services,

including the value of tropical habitats, are not only partial but are also based on current use patterns. They also assume that ownership, access and use of forest resources remain unchanged. There is a need for normative valuation to determine the ownership and access regimes, and the configuration and combination of uses that will maximize the net present value of ecosystems from different perspectives: local, national and global. Furthermore, estimation of current values and their capitalization over time at a fixed discount rate assumes that neither these values nor the rate of discount will change over time. As incomes grow, as technology and tastes change, certain use values (e.g. fuelwood and non-timber products) may diminish while others such as ecotourism values may increase. Indirect values such as ecological services and non-use (existence) values are likely to increase as incomes rise and the supply of habitats and biodiversity are reduced. On balance we would expect conservation values to rise relative to development values (Krutilla and Fisher 1985; Barrett 1992). On the other hand, to the extent that environmental concerns produce an environmental drag on the economic growth, the discount rate ought to be lower in the future than at present (Weitzman 1994). The implication of both the growth in relative conservation values and of the lower future discount rates is a higher net present value for conserved habitats.

It has already been observed that people from different cultures and different income levels value environmental resources differently. Attitudes to conservation are culturally specific. There is, as was remarked in Chapter 12.2, evidence that conservation in some 'traditional' societies carries a higher relative weight than in many 'modern' societies. But differences in empirical estimates of value based on willingness to pay are dominated by differences in income. This is partly because environmental amenity is a superior or luxury good, and partly because measures of willingness to pay are first and foremost measures of ability to pay. In modern societies, it appears that the higher the income, the greater the willingness to pay for conservation. This can be shown by the high income level of people who belong to organizations such as the US-based National Audubon Society, Wilderness Society and The Nature Conservancy. In traditional societies, even though conservation may have a very high relative value, low mean incomes imply low levels of willingness to pay.

The point has been made repeatedly that, because of the subjective nature of the valuation process in all cultures, the private valuation of ecosystems need not be correlated with the social opportunity cost of the services deriving from those systems. Indeed, it is often the case that higher non-use values are correlated with lower use values. For example, many of the national parks in North America are on land of low accessibility and/or low biological productivity, e.g. the American and Canadian Rockies, the

South Dakota 'Badlands', the canyon areas of Colorado and Arizona, and the Florida Everglades. In contrast, the most fertile land, the Great Plains, has the lowest aesthetic value. This is also true in Australia, where reserved land is sometimes very low in biological productivity. Traditionally, people seem to value grassland ecosystems less than mountains and forests, although there is a growing appreciation of prairies in the United States. It is also the case that the preservation of grasslands with a large variety of 'big-game' living on them, as in East, Central and Southern Africa and South Dakota, has been high on the conservation agenda.¹⁰ A preference for savannah forests and grasslands rather than denser forests may be found in northern Australia, where aborigines set fire to plant growth given the opportunity.

People who value wilderness preservation highly in general may value alternative ecosystems differently. Evidence of these priorities can be seen in the periodic surveys that environmental groups may carry out among their members. The Sierra Club, a large conservation advocacy group in the USA, can show that their members have consistently felt very strongly about ANWAR (Alaskan National Wildlife Arctic Refuge), although most have not visited the northern slope of Alaska and do not plan to. Many valuations also run contrary to the scarcity of the resource. Some people value arctic or desert wilderness much more highly than tropical or temperate wilderness, even though pristine Arctic and severely arid ecosystems are in relative abundance.

The fact that economists agree on the importance of estimating the true value or social opportunity cost of ecosystem use does not, therefore, imply that the outcome will necessarily provide a ranking of ecosystems that is consistent with the ranking obtained from an ecological analysis. This is partly because of the existence of non-use values, but it is also because many of the methods devised to capture non-use values, particularly those based on stated preference or constructed markets, cannot correct for the distorting effects of the institutional and informational conditions that make the exercise necessary in the first place. Contingent valuation is designed to elicit the private valuation of resources for which no markets exist, and hence is based on a set of relative prices, and a distribution

of income and assets which are a consequence of the externalities that make valuation necessary.

The presence of non-use value may imply the existence of an important capturable benefit to conservation over and above its effect on the flow of useful goods and services. The latter form only a lower bound on the social value of biological resources. However, it is important to emphasize that these are precisely the values that are most likely to be missed if the method of valuation is one that relies on stated preferences. The point made in the introduction to this section is that if we are to uncover the value of biodiversity, the mix of organisms, we need to understand the role of species in mediating the key structuring processes of ecosystems over a range of environmental conditions. This requires specification of ecological-economic production functions, and work on these is at a very early stage in its development. It also requires that we obtain not just snapshots of the value of ecosystem functions, but time series that show how the value of such functions is changing.

12.6.5 Concluding remarks

- The value of ecosystems derives from their role as habitat, and in mediating ecological functions, protection functions, waste assimilation functions and wider functions such as microclimatic stabilization and carbon storage. These environmental functions all indirectly support economic activity and human welfare. Tropical forests, for example, provide a diverse range of functions and services. **Direct use values** of forests include timber, non-timber forest products, medicinal plants, plant genetics, hunting and fishing, recreation and tourism, and education and human habitat. **Indirect use values** of forests include soil conservation and soil productivity (though nutrient cycling), soil conservation and watershed protection with derivative services of water supply and storage, flood control, microclimatic effects and carbon sequestration. **Option values** include the potential value of habitats for future (direct or indirect) use.
- Where the conservation values of ecosystems are outweighed by their development value, loss of ecosystem function may be avoided only if there is a mechanism for enabling users to appropriate the benefits of conservation. Options include **debt-for-nature-swaps** and **transfers**, whether under bilateral or multilateral aid programmes or under the **Global Environment Facility**.
- Indirect and passive use values of ecological services are likely to increase as incomes rise, and the supply of habitats and biodiversity is reduced. This implies that **conservation values** may be expected to rise relative

¹⁰ A major US environmental organization, The Nature Conservancy, has been funding a number of prairie conservation projects in the US Midwest. Additional efforts to maintain prairies are sponsored by the main Chicago-area Arboretum in Batavia, Illinois, and by Fermi Laboratory, known as the National Accelerator Laboratory. These prairies provide reasonable examples of existence value. People cannot do anything in them except walk along certain paths. Access is free so that no one profits from them, and their recreational value is not captured in a market.

to development values. Conservation of genetic resources should be evaluated along with other goods and services provided by ecosystems, and should form an integral part of land use and management.

- Effective biodiversity conservation depends on the valuation of all goods and services provided by ecosystems in order to determine the configuration and combination of uses that best satisfy the interests of society.

12.7 Valuation in the conservation of biodiversity

12.7.1 The goals of conservation

The distinction between the private and social value of biological resources and the mix of those resources, biodiversity, turns out to be important for very practical policy reasons. The proximate causes of biodiversity loss are to be found, in the main, in the stresses which lead to a loss of ecosystem resilience (of which habitat destruction is a special case). But the underlying causes are to be found in the divergence between the private and social valuation of resource use. As is shown in Chapter 12.5, the cost of forest clearance to the user is frequently not the same as the cost of forest clearance to society, and the result is deforestation in excess of the socially optimal rate. Even though our ability to generate good estimates of the social value of biodiversity is still severely restricted, it is often possible to identify the direction of bias in the current conditions, and that is enough to motivate a change of policy in the right direction.

The policy implications of earlier Sections (5 and 6) on biodiversity in ecosystem functioning are simple but very powerful. They are that the principal objective in the biodiversity problem is not the preservation of a particular set of species now threatened with extinction, but the conservation of the resilience of those ecosystems on which human activity depends. It is this which underpins the ability of those systems to continue to provide valuable ecological services. And the value of biodiversity as distinct from the value of individual biological resources lies in its role in the provision of ecological services. Preservation and conservation are not the same thing.

In economic terms the demand for biodiversity derives from demand for such ecological services. An individual species harvested from some ecosystem may, for example, be valued for specific properties that make it useful in either production or consumption. But the biodiversity of that ecosystem will be valued because it is necessary to the production of the individual species. If not all species in an ecosystem are necessary for the health or resilience of that ecosystem, then not all species will be positively valued. Indeed, if the deletion of some species is judged to be necessary for the health of that system – the smallpox virus,

for example – then that species will be negatively valued (it will be a ‘bad’ from the point of view of humanity).

It is worth re-emphasizing that even if demand for species is motivated by their use in consumption or production, it still involves ethical judgements. One of these has already been alluded to. It relates to the rate at which the future costs of present actions are discounted. A second relates to the connection between the individual and the collectivity. We have already remarked that discounting implicitly involves ethical judgements about inter-temporal or inter-generational equity, and therefore about the responsibility that the present generation should bear for future generations (Goodin 1982). Positive discount rates (over and above the rate at which the flow of goods and services is increasing through economic growth or natural regeneration) imply, at the very least, indifference to the welfare of future generations. Dasgupta and Heal (1979), going further, argued that the discounting of the irreversible future costs of some decision implies that the impoverishment of future generations may be interpreted not just as an incidental outcome, but as a positively desirable result of the decision. Economists tend to be less critical of discounting of this sort – known as utility discounting – now. But the fact remains that utility discounting does involve an ethical judgement about inter-generational equity, and this does vary between countries and social groups as do other aspects of social and private preferences. Wherever the utility discount rate is inconsistent with the rate derived from the growth potential of the relevant capital stock, including the stock of natural resources, the sustainability of economic development is at risk.

The ethical problems raised by these two questions are the subject of a continuing debate. Indeed, they are a large part of what still divides economics and ecology. At issue is the view that if the existence of the component parts of a system is contingent on the health of the whole, as is the case in an ecological system, then the ‘sovereignty’ of any one component of the system – the consumer in this case – may only be exercised within bounds (Perrings and Opschoor 1994). Indeed, the responsibility that accompanies consumer sovereignty is what lies behind the call for a new ethic or morality to govern the relation between the individual and the public good (see, for example, Regan 1986; Wilson 1988; Przewozny 1991).

Protecting the interests of future generations has two major implications for policy that are worth making explicit. First, the aim of a strategy for the sustainable management of wild resources should not be to preserve those resources in the existing state, but to protect the capacity of the ecosystems to which they belong to function over a wide range of environmental conditions – to protect the resilience of those systems. The fact is that conservation does involve trade-offs in the same way as any other resource allocation strategy, and these need to be

considered directly. Preserving wild resources through nature reserves and other protected areas may be an important short-term step where such resources are threatened with immediate extinction, but it does not even begin to address the main problem. Nor is it feasible to protect the resilience of critical ecological systems by excluding human users of wild resources. The goal of a sustainability strategy should not be to protect all wild resources in some areas only and irrespective of cost (in terms of forgone development opportunities), but to ensure that development does not threaten critical biodiversity thresholds in all areas.

Second, it is necessary to create economic incentives that reduce the differences between the value of wild resources to the private individual and their value to society as a whole. That is, it is necessary to internalize the external costs of the use of biological resources. A precondition for this is the valuation of biological resources. But valuation clearly is not enough. What is also required is the development of effective institutions. To be effective in an evolving and only partly understood ecological-economic system, institutions have to be adaptive. Being adaptive means, among other things, being able to respond to environmental feedbacks before those effects challenge the resilience of the entire resource base, and the economic activity that depends on it. Institutions need to be constructed which safeguard the resilience and functionality of ecosystems by safeguarding the resources which support that resilience. That is, it is necessary to bound economic activity in a way that minimizes the risk of irreversible damage to the systems on which human activity depends. While many recent institutional innovations tend to do just the opposite, there are success stories from both traditional and contemporary societies from which we can learn. In the final chapter of this section we consider the policy implications of the valuation of biological resources discussed in earlier chapters.

We begin, however, with a cautionary note. While economists have begun to grapple with the valuation of non-marketed environmental resources, it should be clear from this review of the state of the art that we are a long way from having identified let alone addressed all the issues it raises. The current set of estimates reflects very large differences not just in valuation methodology, but also in the conceptualization of the problem. There is no consensus on the very important question of existence value, for example. Indeed, the jury is still out on both the conceptualization of use, passive use and non-use values, and the appropriate methodology for estimating these values.

A second point is that the economists' approach to valuation is driven by the perception that market prices induce an inefficient allocation of biological resources. But the criterion of efficiency – the objective against which to judge the performance of different societies – remains ill-

defined. Sustainable development is not a well-defined objective, though it is an often stated one. This is not, of course, a problem that is unique to the valuation of non-marketed resources, but if we are interested in determining the social opportunity cost (as distinct from the private value) of non-marketed environmental resources, it is one that has to be addressed.

12.7.2 Protected areas, conservation and development

It is still the case that most conservation efforts, both nationally and internationally, begin and end with the designation of protected areas (national parks, wildlife reserves and so on). The point was made earlier that while this may be a necessary part of any strategy to conserve biodiversity, it is far from sufficient. Conservation requires the protection of sufficient diversity to underwrite the resilience of ecological systems everywhere, not just in protected areas. Hence an important part of any strategy for the conservation of biodiversity is the generation of appropriate incentives for resource users both inside and outside protected areas. More particularly, it is necessary to generate appropriate incentives and to undertake specific initiatives at the local level to complement international, national or regional policies. In recent years this has led to revisions in the strategy for development and management of protected areas, with an emphasis on the need for local participation in conservation measures and the benefits they generate.

McNeely (1993) argues that the traditional approach to setting up protected areas and managing biological resources has sometimes worked against the interests of local populations. Their traditional rights of access to resources in protected areas are usually abrogated by the state. The responsibility for managing biological resources has often been removed from local people, communities and leaders and instead transferred to central government agencies in distant capitals. As a result, the mainly poor and rural communities in the vicinity of national parks and protected areas generally bear the brunt of the forgone economic opportunities associated with conservation measures – with little or no compensation in return. The consequence is often illegal and/or 'open access' exploitation of resources, and increased conflicts between local people and the state.

In recent years, the traditional 'top-down' approach to conservation management has been revised to encourage more community-based conservation. Two general approaches seem to have been advocated (Wells and Brandon 1993). First, *buffer zones* have been delineated and established around park boundaries, as sites for both conservation and development-related activities. Second, new approaches to park and protected area management are being promoted to encourage greater *local participation*. The result has been a proliferation of projects in recent

years attempting to link biodiversity conservation with community-based development.

Wells and Brandon (1992, 1993) have classified all these initiatives that attempt to enhance biodiversity conservation while simultaneously attempting to address the needs, constraints and opportunities of local people as *integrated conservation development projects* (ICDPs). They reviewed 23 of the leading ICDPs in Asia, Latin America and Africa in terms of their effectiveness in achieving their dual objectives of community-based development and biodiversity conservation.

On the whole, their conclusions are not encouraging. Despite its rapidly growing popularity, the overall contribution of the ICDP approach to biodiversity conservation has so far been limited. For example, the buffer zone approach has failed in part because most protected area management agencies have no legal authority to establish or manage buffer zones, outside or inside park boundaries. Similarly, attempts to encourage participation have faltered because most ICDPs have treated local people as passive beneficiaries of project activities and have not involved them in decision-making related to the process of change and development.

The relative ineffectiveness of ICDPs can be traced to four important factors:

- Most ICDPs have been operational for less than five years and are therefore at a relatively early stage of implementation.
- Many ICDPs are operating on very modest scales and with small budgets (some less than US\$50 000 annually), while attempting to implement ambitious and wide-ranging programmes aimed at poverty alleviation, environmental education and conservation in numerous small communities spread over large areas.
- Many ICDPs should be regarded as demonstration projects and cannot be expected to contribute significantly to biodiversity conservation as stand-alone initiatives; their value will largely come through showing what is possible and encouraging replication elsewhere.
- The ICDP approach is innovative and experimental; there are few precedents for linking conservation and development goals within single projects, and a period of learning and making mistakes is inevitable.

Nevertheless, Wells and Brandon (1993) conclude that in spite of these difficulties and shortcomings the ICDP approach should not be abandoned. ICDPs, they argued, 'must be reinforced and expanded simply because there seem to be no other choices... innovative, well-designed projects at carefully selected sites that constructively

address local people-park relationships are essential to the conservation of biodiversity and thus to sustainable development. Workable buffer-zone arrangements and more effective local participation will be key elements of such projects'.

Southgate and Clark (1993) take a slightly more pessimistic view of ICDPs, particularly with regard to biodiversity conservation in South America. The authors condemn the rather 'naive' view that people who live in tropical forests always have a strong economic interest in keeping habitats intact, and note that for proponents of ICDPs, the idea that local communities are not always willing partners in the campaign to save biological diversity is disheartening. Particularly in Amazonia, conflicts between locals, who resent the loss of access to resources, and park managers and supporters often grow acute, and rarely are these conflicts resolved in favour of conserving flora and fauna.

Where conservation is promoted, it is usually because of the potential for tourism development, e.g. the Galapagos National Park of Ecuador and the Mayan ruins at Tikal in the Petén tropical forests of Guatemala. Those officially designated natural reserves in South America that still remain relatively untouched will not be so for long. As local populations multiply and as infrastructure development begins to encourage settlement by outsiders, pressure on natural ecosystems will increase and the survival of parks and reserves may be threatened. Southgate and Clark argue that this process is not encouraging for ICDPs. Establishment of these initiatives to encourage participation by local populations must overcome powerful incentives for habitat and land conversion by the same communities. ICDP activities can themselves promote environmental degradation, e.g. improved roads, trails and infrastructure can make it easier for local people to penetrate previously inaccessible forests and protected areas.

In short, where the incentives for 'nutrient mining' and land conversion are strong among local communities, then successful implementation of ICDPs and park protection initiatives will be extremely difficult. Even attempts to set up extractive reserves or, buffer zones, or to demarcate park boundaries are unlikely to withstand the onslaught of loggers, farmers, ranchers and prospectors. Southgate and Clark suggest that natural ecosystems and protected areas can best be saved through promoting environmentally sound intensification of crop and livestock production in areas away from forest and agricultural frontiers.¹¹

¹¹ Southgate (1991) has conducted a statistical analysis that illustrates this point: in Latin American countries where crop and livestock yields have improved, land-use conversion has been mitigated, whereas in countries with poor productivity trends land conversion has increased.

Although field activities such as ICDPs are important for saving threatened habitats in developing countries, they are not sufficient and certainly not a substitute for improving sustainable production, income and employment in other areas, including urban zones and rural areas where agriculture is already well established. The authors claim that, unfortunately, most organizations are far more interested in seeing ICDPs and related initiatives funded and implemented than they are in projects to increase overall agricultural productivity.

The important focus of integrating economic development with biodiversity conservation is the generation of the correct incentives for biodiversity conservation while at the same time discouraging perverse incentives that work against conservation. Ultimately, this must operate at the *local level*, where the millions of farmers, hunters, herders, ranchers, fishing folk and harvesters interact with the natural environment every day. As argued by McNeely (1993), overcoming the damage caused by perverse incentives will require new initiatives to promote conservation, applied at a series of levels and in a number of sectors. Changing behaviour at the local level will require reasonably comprehensive packages of *direct incentives* (tax breaks, subsidies, grants, compensation for animal damage, interest-free loans, differential fees and differential access to resources), *indirect incentives* (the application of fiscal, service, social and natural resource policies to specific conservation problems) and *disincentives* (penalties, punishment and other forms of law enforcement accompanied by public information). ICDPs are clearly only part of the solution and should not be seen as the 'panacea' of biodiversity conservation, but they do provide an important lesson: conservation measures are likely to be most successful when they provide real and immediate benefits to local people.

More generally, under the right conditions, efforts to promote community-based conservation can be an effective indirect incentive that can form an important part of the overall 'package' comprising a biodiversity conservation strategy. Such efforts are diverse and can include building community-level conservation institutions, encouraging community involvement in both management and decision-making about resource use, promoting ideas of sustainable agriculture and forestry, conserving and promoting traditional knowledge, providing education to local people and providing special development actions to villages surrounding protected areas.

12.7.3 *Incentives and the appropriation of value: the local problem*

To illustrate the elements required of a local biodiversity conservation strategy, consider the case of tropical forests. Many governments have created economic incentives that powerfully accelerate the rate of deforestation, stimulating

rapid depletion of timber resources and encouraging the conversion of forest land to agriculture and other uses. These include inappropriate forest revenue systems which (a) leave enormous economic benefits to timber concessionaires, (b) provide little incentive for sustainable forestry, and (c) encourage highly selective and destructive harvesting (Repetto 1988). These policies are often compounded by poor enforcement of logging regulations and underemphasis on the non-timber products obtainable from tropical forests. To stimulate local economies, governments have overprotected timber mills and wood processors, leading to inefficient industries which exert strong pressure for enough logs to maintain their production levels irrespective of economic or environmental considerations (Repetto 1988; Repetto and Gillis 1988). Many governments have also nationalized their forest lands, superseding traditional rights of local authorities and communities. Although intended to strengthen control, this has more often undermined local rules governing access and use, removed local incentives for conservation, and granted responsibility to forestry agencies which are totally beyond their capacity to meet (Repetto 1988).

But in many countries, non-forestry policies have caused greater forest destruction than misguided or misapplied forestry policies (Repetto 1988). Most obvious are agricultural programmes under which forest is cleared for estate crops. Closely related are public investments in mining, dams, roads and other large infrastructure projects that destroy forests. Then come tax, credit and pricing policies that stimulate private investment in competing land uses. Generous government subsidies to competing land uses have resulted in the rapid conversion of forest lands, often to uses that are economically inferior and even non-viable without continuing government support. Large-scale agricultural settlements in forest areas, carried out at enormous cost to the government, have failed in several countries after deforesting huge areas (Repetto and Gillis 1988).

There are important connections between deforestation and failed development policies. Pressures on natural forests are reduced when communities achieve adequate growth in rural output and employment, begin to convert from wood as an energy source to electricity and petroleum products, and experience declining population growth rates as birth and death rates decline and young workers are drawn off into expanding urban industries. By contrast, economic stagnation and poverty inevitably accelerate deforestation (Repetto 1988). Economic policies that have retarded development include deeply overvalued exchange rates, negative real interest rates, and flagrantly distorted commodity prices. Such policies often impose heavy penalties on the rural sector as the prices of agricultural outputs are lowered, thereby attracting less private sector

capital, reducing employment and leading to further pressure on unconverted forest land (Repetto 1988).

In Latin America, generous incentives made available to promote extensive cattle ranches have acted as convenient tax shelters for corporations and wealthy investors. While investors have gained, the ranches have failed both economically and ecologically (Browder 1988; Binswanger 1989). Government-subsidized road construction has facilitated access to markets and further increased profits from logging and from converting forest lands for agriculture or grazing. Resettlement of people to the areas opened up by roads has often been seen as politically preferable to genuine land reform involving the redistribution of agricultural lands. Migrants often risk losing their title or other legal rights if they do not clear the forest. Such policies are common where governments in impoverished, overcrowded and polluted cities perceive sparsely populated forest lands as a means of reducing population pressure and providing new employment opportunities (McNeely 1988).

We have already indicated that current market prices do not reflect the environmental consequences of these policies. A corollary of this is that the systems of national accounts that inform both macroeconomic and microeconomic policies at the national level also neglect the environmental consequences of economic activity. The aim of national income accounting is to provide an information framework suitable for analysing the performance of the economic system. But there is a dangerous asymmetry in the way natural resources are measured in national income accounts. A country could exhaust its mineral forests, cut down its forests, erode its soils, pollute its aquifers, and hunt its wildlife and fisheries to extinction, but national income and economic growth as conventionally measured would not be affected. The implicit (inappropriate) assumption is that natural resources – including biodiversity – have no marginal value (Repetto *et al.* 1989).

Current evaluations of national economic performance and estimates of macroeconomic relationships are seriously distorted by failure to account for the depletion of natural resources such as biodiversity, forests, topsoils and fisheries, as well as energy and mineral reserves. Official statisticians and their clients have resisted the demand to reform inadequate national accounting systems, citing the need to refine methodologies and data collection (e.g. Ahmad *et al.* 1989; Lutz 1993). But natural resource accounting analyses by the World Resources Institute for Indonesia (Repetto *et al.* 1989), Costa Rica (Solórzano *et al.* 1991) and the Philippines (Cruz and Repetto 1992) have already highlighted the need to reassess the economic performance and development patterns of these countries, showing how natural resource assets were depleted to finance current consumption and the acquisition of relatively unproductive industrial capital. These exercises

show that natural resource depletion rates are often so great that even partial estimates for the principal sectors provide important insights into economic performance. Macroeconomic analyses based on accounting frameworks that ignore this information will almost inevitably lead to erroneous conclusions and faulty prescriptions.

12.7.3.1 Structural adjustment programmes and policies

National policies affecting the environment are not, of course, static. Many developing countries underwent economic reform necessitated by acute fiscal and current account deficits in the late 1970s and early 1980s, adopting World Bank and IMF prescriptions for structural adjustment. These packages were intended to change the whole set of relative prices facing producers and consumers, reform underlying institutional arrangements, affect overall levels of public sector investment in infrastructure, and promote private sector activities to increase employment (Reed 1992). So far, however, only a handful of studies have explored the fundamental and far-reaching environmental impacts of structural adjustment programmes (Cruz and Repetto 1992).

Reed (1992) describes numerous examples of economically inefficient use of natural resources and environmental degradation which can be linked to structural adjustment policies in Côte d'Ivoire, Mexico and Thailand, although these environmental impacts have proved variable – some good, some bad – and difficult to untangle. Three generalizable features emerged: (a) the reduction in public expenditure programmes imposed by fiscal restraints reduced the budgets of agencies protecting the environment, (b) reduced credit to small rural investors led to lower on-farm investments and declining agricultural yields, countering efforts to stabilise the agricultural frontier – particularly in the absence of effective land tenure systems, and (c) institutional constraints negated efforts to correct price distortions in the forestry, irrigation and energy sectors.

A recent analysis of the relationship between structural adjustment and the environment in the Philippines has challenged the conventional view that the most important environmental impact of the debt crisis of the early 1980s was to intensify resource exploitation for export production. In fact, the most serious result was massive unemployment and income decline attributable to the debt crisis and stabilization policies, which led to vastly increased numbers of workers migrating to the open access resources of the uplands and coastal areas, with consequent deforestation, soil erosion, destruction of coastal habitats and depletion of fisheries (Cruz and Repetto 1992).

The macroeconomic accounting frameworks and analytical models currently used by international development agencies generally assume away any possible environmental effects of macroeconomic policy instruments such as taxes, interest rates, tariffs and

exchange rates, and levels of public spending. Using such analytical tools, it is impossible even to examine whether particular policy changes would have beneficial, mixed or adverse effects on natural resource use and environmental quality. There is an acute lack of models that relate natural resource use and environmental impacts to macroeconomic policy change. Until these are developed and used, policies will continue to be based on assumptions of no environmental impact (Cruz and Repetto 1992).

Under current conditions in most developing countries, the remaining tropical forest habitats have less than an even chance of surviving the next several decades because of the simple but critical fact that the local benefits of conservation fall far short of local opportunity costs (Wells 1992; Panayotou 1994a). The local benefits from conserving forests are low because only a fraction of their direct value and associated goods and services (fuelwood, non-timber goods, and local watershed protection) accrue to the local populations. The rest accrue to distant beneficiaries outside the immediate local area (soil and water conservation, ecotourism and timber production) and outside the country (biodiversity, carbon sequestration).

The local opportunity costs of conserving forests in developing countries are relatively high because of (a) the general lack of the means (secure land title, access to credit, technology, etc.) to practice sustainable agriculture and to raise productivity on existing farmland and (b) the paucity of non-land-based economic activities and employment opportunities, especially in rural areas; and (c) the pervasiveness of direct and indirect subsidies for forest liquidation and land conversion to other uses, which artificially raise the private opportunity costs of conserving forests to local populations.

The shortfall of local benefits from conserving forests to cover the opportunity costs constitutes a very potent incentive for forest conversion and renders protection very difficult and costly to enforce. To conserve forests it is necessary to alter the incentive structure from one that favours forest depletion and conversion to one that favours conservation and sustainable management by raising the local benefits from forests and lowering opportunity costs. For each of the goods and services derived from or associated with biodiversity conservation, several economic and financial incentives could be devised to capture and internalize these benefits to local populations. The following is a small sample of domestic and international incentives and financing mechanisms for biodiversity conservation.

12.7.3.2 Raising local benefits

The benefits to local populations from conserving forests can be enhanced by (a) recognizing their special relationship to natural forests, sanctioning customary rights and containing access by outsiders and (b) internalizing to

the local communities the external (both national and global) benefits of forest conservation through mechanisms that fully value and transfer part of this value to the local population; and (c) by involving the local communities in the protection and management of forests.

12.7.3.3 Lowering local opportunity costs

The opportunity costs (forgone benefits) to local populations from forest conservation (non-depleting, non-converting forests) can be lowered substantially by (a) renewing the subsidies that artificially inflate these benefits from depletion and forest conversion (e.g. granting of title for land clearing, underpricing of timber concessions etc.); (b) providing the local populations with the means (land tenure, access to credit, technology and markets, education, etc.) to practice sustainable agriculture and raise productivity on existing cropland; and (c) by making available and accessible alternative non-land based employment opportunities, to rural populations through promotions of labour-intensive industries and investment in human resource development.

12.7.3.4 Lowering forest protection costs

Increasing the benefits and lowering the opportunity costs to local population of conserving forests would automatically lower the pressures on the remaining habitats and thereby reduce the costs of effective forest protection. These costs can be further reduced by directly involving the local populations (as forest guards, tour guides, collectors of non-timber forest products and scientific samples) in the protection and management of forests for sustainable production of goods and services. Involvement of local populations would lower the costs of effective protection because (a) they have intimate knowledge of the forests, its functions and the threats it faces; (b) they are continuously present and can be motivated to police themselves; and (c) being among the lowest socioeconomic groups, local communities can do the job at the lowest possible cost.

12.7.3.5 Water fees as forest conservation incentives

Watershed protection is a major service provided by tropical forest habitats. While local communities may derive some benefits from local watershed protection, the principal beneficiaries tend to be downstream farmers and urban and industrial centres who are protected from floods as well as supplied with naturally regulated and larger than otherwise quantities of water. Since these beneficiaries are currently not charged for the watershed services of national parks and protected forests, watershed protection and associated biodiversity conservation remain underfunded; and, since local populations receive no benefits from the watershed services of the forests they have no incentive to take these values into account in their behaviour towards

the forest. The watershed value of forests can be captured and internalized to the local population through efficient water and hydropower pricing that includes a watershed protection charge. The revenue from this charge is then passed to local communities and individuals entrusted with the protection of the forests in water catchment areas. At the minimum, water charges should be an important source of funding for conservation of major watersheds as well as an economic incentive for conserving scarce water resources. Dunoga Bone combined Irrigation and National Park System in Sulawesi, Indonesia, is an example of how water fees can serve as a financing mechanism for conserving biodiversity. A watershed protection charge, if included in the price of hydroelectricity in countries such as Costa Rica, El Salvador, Sri Lanka, Vietnam and Laos (which derive most of their electricity from hydro-power), can serve both as an incentive to conserve energy and as a financing mechanism for watershed protection and the development of alternative opportunities for shifting cultivators and other forest encroachers.

A variant of this mechanism is the issue of water rights to people living in watershed areas in exchange for protecting a specified piece of forest. Downstream farmers and urban centres can access the water of dams drawing from the catchment area by buying water or leasing water rights from the protectors of the watershed; others living in and around the catchment area who refrain from encroachment and destruction, while not actively involved in watershed protection, could also be given water rights but to smaller quantities of water.

12.7.3.6 Internalizing ecotourism benefits

The benefits from ecotourism associated with forest conservation often flow to distant beneficiaries in urban areas and overseas, while the local people resent these new claimants to their heritage. Under these conditions, encroachment tends to intensify rather than abate. Ecotourism can become an important incentive for conservation if a large portion of the derived benefits flow to the local population. This can be done not only by engaging local people as forest guards and tour guides but also by issuing ecotourism franchises to local communities and allocating a portion of ecotourism revenues to the development of alternative employment opportunities to reduce the pressure on tropical forests.

12.7.3.7 Reforestation incentives

An interesting forest conservation incentive operates in Costa Rica, known as the transferable forest conservation tax credit. Land owners who choose to keep their land under forestry (or plant native species) receive a tax credit (i.e. they can deduct part of the costs from their taxes). This scheme benefits particularly bigger, wealthy land holders who pay a significant amount of taxes. To enable small

land holders to share in the benefit of the scheme, the government introduced a transferable tax credit system: small-holders who keep their land under forests earn tax credit which they can sell to wealthy taxpayers with high taxes to offset. The annual nature of both the tax credit and the investment (maintenance of land under forest) provides a continuous incentive to keep land under forests. Yet, a differential land-use tax could have achieved the same result more directly without a financial cost to the government.

12.7.3.8 Differential land use tax

In Germany land uses are classified in a number of categories from environmentally most beneficial (e.g. natural forest) to environmentally most destructive (e.g. industrial site). A charge is imposed on the land-owner when he/she changes land use from a higher to a lower class. The more the steps of environmental downgrading, the more the charge (charge \times number of steps). For example, the charge for downgrading from natural forest to industrial site is far greater than from natural forest to managed forest. The effect of this differential land-use tax is to internalize the environmental costs of forest conversion and land-use change. Corresponding environmental upgrading of land (e.g. reversion of agricultural land to forest) may receive a subsidy.

12.7.3.9 Environmental bonds

Environmental performance bonds are economic instruments that aim to shift responsibility for controlling deforestation, monitoring and enforcement to individual producers and consumers who are charged in advance for the potential damage. Often the state is saddled with huge bills for reforestation after logging. Environmental bonds ensure that: (1) logging and extractive industries take adequate measures to minimize the environmental damage caused by their activities and preserve biodiversity values and ecological services; (2) they effect restoration of residual damage in the most cost-efficient manner; and (3) adequate funds are available for the restoration of damaged environments by anyone who fails to comply. Environmental performance bonds are increasingly employed in mining and logging concessions in Malaysia and other Southeast Asian concessions. Environmental bonds need not be a constraint on economic activity, as they can be invested in interest-bearing accounts or replaced by bank guarantees. It turns out that a variant of performance bonds has considerable potential not just in protecting society against the misuse of environmental public goods, but in reducing the uncertainty associated with innovative activities. It is possible to construct an economic incentive that will have the effect not of correcting for externalities observed *ex post*, but encouraging resource users to identify externalities *ex ante*.

Environmental Assurance Bonds have been recommended both as an insurance where problems of irreversibility and fundamental uncertainty prevent the actuarial assessment of the risks associated with the use of public environmental resources, and as incentives to resource users to research the environmental implications of their actions (Perrings 1989b; Costanza and Perrings 1990; Farber 1991).

12.7.3.10 *Forest compacts*

These are voluntary obligations (commitments) drawn and undertaken by individual developing countries with the support of developed countries to engage in policy reforms, conservation and investment programmes that would achieve specified targets of forest preservation and sustainable management over a specified period of time in exchange for the transfer of financial and technology resources from developed countries to support these reforms. The participating countries could in turn be given credit against CO₂ reduction and forest protection obligations undertaken under international conventions.

12.7.3.11 *Carbon offsets*

This is a special type of forest compact jointly drawn and implemented by a developed country entity such as a power utility and a developing country forest company, a Forestry Department or any other forest donor. Under this type of joint implementation, the power utility or other sources of CO₂ emissions finance a shift to reduced impact logging techniques, enrichment planting or reforestation or forest conservation in a developing country in exchange for credit for the carbon saved or sequestered by the funded forestry activity. The potential benefits are substantial (arising from differential costs of CO₂ reductions between developed and developing countries) and are shared between the parties involved (both private and public). While several such pilot offsets have been initiated in recent years (e.g. New England Electrical System with the Sabah Foundation; Applied Energy Systems of Virginia with Guatemala), North–South carbon offsets have not yet been sanctioned by governments and the global community as legitimate means of meeting CO₂ reduction obligation under the Climate Convention. The Conference of the Parties, meeting in Berlin 28 March–7 April 1995, adopted a resolution to permit a pilot phase of joint activities between the parties but with no credit to any party as a result of greenhouse emissions reduced or sequestered during the pilot phase. Despite this development, carbon offsets and other joint activities are receiving sufficient interest by both North and South to warrant further study and experimentation. Carbon offsets provide one mechanism through which the global value of carbon sequestration can be internalized to the local populations of developing countries.

12.7.3.12 *Transferable development rights*

A final measure worth discussion is the transferable development right (TDR) used for the preservation of historical sites, and more recently, proposed for conservation of biodiversity (Panayotou 1994b). Tropical countries could set aside habitats for biodiversity conservation and divide each habitat into a number of TDRs, corresponding to an area unit of, say, a hectare. Each TDR would state the location, condition, diversity, and a degree of protection of the habitat and any special rights that it conveys to the buyer/holder. TDRs could then be offered for sale both locally and internationally at an initial offer price that covers fully the opportunity cost of the corresponding land unit (i.e. the net present value of the income stream of the forgone development opportunity). It is preferable to start at a relatively high price to test the market, since undervaluation is irreversible (following sale) while overvaluation is reversible (following non-sale). If the price turns out to be too low to clear the market, i.e. to exhaust the supply of TDRs for a particular habitat, the price could be lowered to attract additional demand or the quality of the TDR could be enhanced by enlarging the area to include additional biodiversity values or by improving its protection and management.

The potential buyers of TDRs include local and international organizations, local and international foundations and corporations, developed country governments, chemical and pharmaceutical companies, scientific societies, universities and research institutions, even individuals in the developed countries who are environmentally minded. The motivation for purchasing TDRs would naturally vary among prospective buyers. Some may have direct use values such as prospecting for new chemicals or pharmaceuticals. Others may be expressing their non-use values through the purchase of TDRs. Some might even buy and hold TDRs if they expect them to rise in value as a result of decreasing supply and increasing demand due to population and income growth or change in tastes and increase in environmental awareness. Certainly every new discovery of a valuable new species, or even a new use of existing species found in a particular habitat would increase the value of the TDRs of that site.

One way in which developed countries can stimulate the demand for TDRs is by providing credits to domestic firms and property owners for the acquisition of TDRs from developing countries against domestic environmental regulations such as building codes, forest harvesting and replanting regulations, environmental emission standards, CO₂ emission controls, etc. A criticism of this method of stimulating the demands for TDRs might be that the conservation of tropical forests would have been accomplished at the expense of the domestic environment in the developed countries. One way around this problem is to tighten environmental regulations from current levels

and then provide offset credits for buyers and holders of TDRs. Another method is by introducing a conservation tax and then allowing people the option to pay this annual tax or purchase and hold TDRs in lieu of the tax. The great advantage of this financing mechanism for the conservation of tropical forests and biodiversity is that it makes the opportunity costs clear and provides a vehicle for the beneficiaries to pay them. The debt-for-nature swaps are rudimentary applications of tradable development rights without the full benefit of tradability and market competition.

12.7.3.13 Other instruments

Non-biodiversity-targeted instruments and incentive measures such as the air pollution trading programme in the USA or water pollution charges in France, may have as great an impact on biodiversity as do measures specifically targeted for biodiversity conservation. The implication is that existing policies could be modified or fine-tuned to improve their performance with respect to biodiversity protection. For example, the tradable fishery quota system introduced in countries such as New Zealand to limit overfishing and to conserve commercial fish species could be modified to reduce the impact of incidental catches on other species and the inter-relationship of species with other aquatic wildlife.

12.7.4 Incentives and the appropriation of value: the global problem

Local market failure describes the inability of existing markets to capture non-market and non-use values of forests, wetlands, etc. within the context of a country or a local area. But there are missing global markets as well. We consider two such global markets which are highly relevant to biodiversity: existence value possessed by individuals in one country for wildlife and habitat in other countries, and the carbon storage values of tropical forests. Global appropriation failure (GAF) arises because these values are not easily captured or appropriated by the countries in possession of biological diversity.

Chapters 12.2 and 12.5 offered the results of some global existence value studies for particular species and habitats based on contingent valuation methods, for several countries. While it is not possible to argue definitively that similar kinds of expressed values will arise for the protection of biodiversity in other countries or for other species, even a benchmark figure of US\$10 per annum for the rich countries of Europe and North America would produce a fund of \$4 billion per annum. This is a significantly larger sum than that which will be available to the Global Environment Facility in its operational phase under the two Rio Conventions and its continuing role in capturing global values from the international water context; and in its role as provider of extra biodiversity conservation

under the Rio Convention (Pearce and Brown 1994).

All forests store carbon so that, if cleared for agriculture, there will be a release of carbon dioxide which will contribute to the accelerated greenhouse effect and hence global warming. In order to derive a value for the 'carbon credit' that should be ascribed to a tropical forest, we need to know (a) the net carbon released when forests are converted to other uses, and (b) the economic value of one tonne of carbon released to the atmosphere. Carbon will be released at different rates according to the method of clearance and subsequent land use. The data suggest that, allowing for the carbon fixed by subsequent land uses, carbon released from deforestation of secondary and primary tropical forest is of the order of 100–200 tonnes per hectare.

The carbon released from burning tropical forests contributes to global warming and recent work suggests a 'central' value of US\$20 of damage for every tonne of carbon released (Fankhauser and Pearce 1994). On this basis, converting an open forest to agriculture or pasture would result in global warming damage of \$600–1000 per hectare; conversion of closed secondary forest would cause damage of \$2000–3000 per hectare; and conversion of primary forest to agriculture would give rise to damage of \$4000–4400 per hectare (Brown and Pearce 1994).

It also seems to be the case that these 'carbon credit' values are larger than many development benefits that would accrue from forest conversion. This suggests that there is scope for a global bargain. The conserved forest is worth more to the global community than it is in its converted state to local 'developers'. If the industrialized countries can transfer a sum of money greater than the converted forest land value but less than the damage cost from global warming, there are mutual gains to be obtained.

The economic valuation of ecosystems and their function and service values is far from complete but it may well be that for some assets, such as forests, global values dominate local values. The implication of this is that schemes for international transfers will be needed to supplement the correction of both local market failures and domestic distortionary practices that contribute to deforestation. Uncertainty remains because the science of global warming has yet to uncover definitive proof of the scale and severity of global climate change impacts. Thus the carbon storage benefits are still probabilistic. Secondly, we do not have a comprehensive set of reliable and valid global existence value estimates for biodiversity. This leaves the issue of appropriation: how are the economic values to be turned into cash, technology or commodity flows to make them 'real' to those who make land-use decisions that cause biodiversity loss?

One of the main difficulties to be faced is that there is much less scope for correcting market failure in international markets than in national markets. Trade

barriers in the industrialized world often exacerbate environmental pressures in developing countries by impeding export of labour-intensive manufactures and forcing these countries to increase exports of unprocessed natural resource-based commodities, thus imposing pressure on indigenous natural resource systems including biodiversity. Eliminating these trade barriers would have significant economic and environmental benefits. Output would expand in labour-intensive processing industries, enabling developing countries to add more value to their exported primary materials and drawing off labour from rural areas into higher-productivity manufacturing employment at a faster rate. Faster employment growth would mitigate poverty and poverty-related environmental problems while growth in alternative sources of foreign exchange earnings would mitigate the over-exploitation of natural resources for export (Repetto 1993).

While export crops may be biologically no more damaging than other crops, it is frequently the case that exporters have little scope for appropriate pricing of domestic environmental resources. Northern demand for the output of Southern environmental resources is frequently cited as a major cause of environmental degradation. For example, about 3 million hectares in the Netherlands are devoted to agriculture. But a Dutch ‘resource consumption audit’ has revealed that another 13 million hectares (an area three times the size of the Netherlands) in other countries is required to meet the demand for domestic consumption and re-export of agricultural products. Increased Dutch demand for tapioca (dried cassava root) has helped stimulate a significant increase in Thailand’s cassava production, which is argued to have contributed to extensive deforestation in northeast Thailand. Other large-scale forest losses can be linked to increasing Dutch imports of soybean from Brazil and oil palm from Malaysia (Netherlands National Committee for IUCN 1988, cited in WRI/IUCN/UNEP 1992: p. 52).

The problem in this case, as in the many others cited in this section, is that the environmental costs associated with the production of traded products in developing countries

are not being included in product prices. If all developing countries were to include the costs of environmental protection in the prices of their exports, especially to the North, they would be able to finance environmental protection (Repetto 1993). However, if any one developing country were to do so it would risk losing competitiveness.

12.7.4.1 Global environmental markets

There are, none the less ways in which international market failure can be corrected through creating global environmental markets (GEMs) (the following remarks on failure correction derive from Pearce 1994b). To begin with, it is useful to distinguish between private and public ventures, and between those that are regulation-induced and those that are spontaneous market initiatives. Public regulation-induced activity arises because of international agreements, such as the Biodiversity and Climate Change conventions; see Table 12.7-1 (Brown *et al.* 1993; Pearce and Brown, 1994). The US Government announced the Forest for the Future Initiative (FFI) in January 1993 under which carbon offset agreements will be negotiated between the USA and several countries, including Mexico, Russia, Guatemala, Indonesia and Papua New Guinea. The aim is for the US Environmental Protection Agency to broker deals involving the private sector.

While not strictly a private enterprise trade, in the Netherlands, the state electricity generation board (SEP) established a non-profit-making enterprise in 1990. FACE (Forests Absorbing Carbon dioxide Emissions) aims to sequester an amount of CO₂ equivalent to that emitted by one 600 MW power station. This is estimated to require some 150 000 hectares: 5000 ha in the Netherlands, 20 000 ha in central Europe and 125 000 ha in tropical countries. At the end of 1993 the actual area had risen to 180 000 ha with the additional area in tropical countries.

In the USA, offset deals are currently not directly linked to legislation, but several have occurred which are clearly a mix of anticipation of regulation and ‘global good citizenship’ (Newcombe and de Lucia 1993). These include

Table 12.7-1: A schema for global environmental markets.

	Regulation-induced	Spontaneous markets
Public/official ventures	Examples: government-to-government measures under joint implementation provisions of the Rio treaties: Norway, Mexico, Poland, GEF	Examples: government involvement in market ventures: Swiss Green Export aid; debt-for-nature swaps
Private sector ventures	Examples: carbon offsets against carbon taxes and externality adders	Examples: purchase of exotic capital; Merck and Costa Rica

the New England Power Co. investment in carbon sequestration in Sabah, Malaysia, through the reduction of carbon waste from inefficient logging activities. The forest products enterprise is run by Innoprise. New England Power estimate that some 300 000 – 600 000 tonnes of carbon (C) will be offset at a cost of below US\$2 tC. Rain Forest Alliance will assist in monitoring the project. New England Power regard the Innoprise project as the first of a series aimed at assisting with the Corporation's plan to reduce CO₂ emissions by 45% by the year 2000. PacifiCorp, an electricity utility in Oregon, is considering reforestation projects and urban tree planting programmes in the US, and an international sequestration project (Dixon *et al.* 1993). Two pilot projects have been announced: (a) a rural reforestation project in Southern Oregon which funds planting subject to a constraint of no harvesting for 45–65 years, at an estimated cost of around \$5 tC; and (b) an urban tree programme in Salt Lake City, Utah at a provisionally estimated cost of \$15–30 tC sequestered. Tenaska Corporation is considering sequestration projects in the Russian boreal forests. Ultimately, some 20 000 ha of forests may be created in the Saratov and Volgograd regions at a cost of \$1–2 tC. Russian partners in the venture include the Russian Forest Service, the Ministry of Ecology and others. Tenaska is also planning reforestation projects in Washington State to complement a project in Costa Rica.

While these investments are aimed at CO₂ reduction, sequestration clearly has the potential for generating joint benefits, i.e. for saving biodiversity as well through the recreation of habitats. Much depends here on the nature of the offset. If the aim is CO₂ fixation alone, there will be a temptation to invest in fast-growing species which could be to the detriment of biodiversity. It is important therefore to extend the offset concept so that larger credits are given for investments that produce joint biodiversity–CO₂ reduction benefits.

Newcombe and de Lucia (1993) have drawn attention to another potentially very large private trade which has global environmental benefits. Investment by the private sector in the developing world is invariably constrained by risk factors such as exchange rate risks, repayment risks, political risks and so on. In so far as this investment benefits the global environment, as with, say, the development of natural gas to displace coal, the existence of the risks reduces the flow of investment and hence the global environmental benefits. But these risks might be shared ('brought down') by having an international agency, such as the Global Environment Facility, provide some funds or services that help reduce the risk. Given the scale of private investment flows, the potential here is enormous. Nor is there any reason why it should not benefit biodiversity, either indirectly as a joint benefit of other investments, e.g. raising agricultural productivity and hence reducing the pressure for land degradation, or directly through afforestation schemes.

Financial transfers may take place without any regulatory 'push'. The consumer demand for green products has already resulted in companies deciding to invest in conservation either for direct profit or because of a mix of profit and conservation motives. The Body Shop is an illustration of the mixed motive, as is Merck's royalty deal with Costa Rica for pharmaceutical plants and Pro-Natura's expanding venture in marketing indigenous tropical forest products. There is, in other words, an incentive to purchase or lease 'exotic capital' in the same way as a company would buy or lease any other form of capital. More generally, environmental sensitivity is becoming a more pronounced feature of private business sector operations, e.g. the 'Environmentally Responsible Business' movement, increased use of environmental audits, eco-labelling of products and the publication of company environmental policy statements.

The deal between Merck and Co., the world's largest pharmaceutical company, and INBio (the National Biodiversity Institute of Costa Rica) is already well documented and studied (Reid *et al.* 1993). Under the agreement, INBio collects and processes plant, insect and soil samples in Costa Rica and supplies them to Merck for assessment. In return, Merck pays Costa Rica US\$1 million plus a share of any royalties should any successful drug be developed from the material supplied. The royalty agreement is reputed to be of the order of 1–3% and is to be shared between INBio and the Costa Rican Government. Patent rights to any successful drug would remain with Merck. Biodiversity is protected in two ways – by conferring commercial value to the biodiversity, and through the earmarking of some of the payments for the Ministry of Natural Resources.

How far is the Merck–INBio deal likely to be repeated? Several caveats are in order here to offset some of the enthusiasm over this single deal. First, Costa Rica is in the vanguard of biodiversity conservation, as its strong record in debt-for-nature swaps shows. Second, the country has a strong scientific base and a considerable degree of political stability. Both of these characteristics need to be present and their combination is not typical of developing countries. Third, the economic value of such deals is minimal unless the royalties are actually paid and that will mean success in developing drugs from the genetic material. The chances of such developments are small – perhaps one in 1000–10 000 of plant species screened (Pearce and Moran 1994). INBio has undertaken to supply 10 000 samples under the initial agreement. There is, therefore, the probability of one such drug being developed. But successful drugs could result in many hundreds of millions of dollars in revenues. Finally, there are two views on the extent to which deals of this kind could be given added impetus by the Biodiversity Convention. The convention stresses the role of intellectual

property rights in securing conservation and is sufficiently vaguely worded for there to be wide interpretation of its provisions. But it also appears to threaten stringent conditions concerning those rights and technology transfer and it remains to be seen how the relevant protocols are worded. If so, parties to the convention may find private deals being turned into overtly more political affairs with major constraints on what can be negotiated (Blum 1993).

Other examples of direct deals on 'biodiversity prospecting' include California's Shaman Pharmaceuticals (Brazil and Argentina) and the UK's Biotics Ltd. (general purchase and royalty deals), while Mexico and Indonesia are looking closely at the commercialization of biodiversity resources.

The demand for direct investment in conservation is not confined to the private sector. The demand for conservation by NGOs is revealed through debt-for-nature swaps, which are further examples of these exotic capital trades (for an overview see Pearce and Moran 1994; Deacon and Murphy 1994).

A great variety of trades is possible, involving both the public and private sectors. For example, consider the general area of resource franchise agreements (RFAs). The general principle of RFAs is that specific land uses in defined zones are restricted ('attenuated') in return for the payment of a premium. At one extreme, if all land uses other than outright preservation are forbidden, the premium equals the rental on the land that would arise in the 'best' development use. If some uses are restricted, the premium will tend to be equal to the differential rent between the unrestricted 'highest and best' use and the rental on the restricted use. The minimum supply price offered by colonizers and host governments will be this differential rent. The demand price will be determined by global willingness to pay for the benefits of attenuating land uses. This is the essence of the comparison made earlier between land prices and global warming damage estimates, for example. Payment of the premium would be, say, annual since an 'up front' payment could result in the host country reneging on the understanding after payment is received. To secure compliance, annual payments would be made in order that they can be suspended in the event of non-compliance.

Such trades are not without their problems. The earlier example of carbon storage values compared land prices with the present value of global warming damage from a tonne of carbon dioxide. Two discount rates are embedded in this comparison: the farmer's and the world's. If payments have to be annual, the present values need to be annuitized. Since it is the farmer who has the property rights, his discount rate will dominate. The relevant comparison will be between annual willingness to pay and annual willingness to accept a premium. Another issue relates to the successional uses of land. The logger should effectively pay a price for land that reflects not just the logging value, but also a residual price if

the land can be sold on to ranchers and farmers. Markets need to work fairly well for the conservation and development values to be compared.

Several authors have suggested franchise-type agreements (Sedjo 1992; Panayotou 1994b). Such development rights could become tradable, just as joint implementation schemes could become open to subsequent bargains leading to a full emissions trading programme. The potential buyers could range from local conservation groups through to international conservation societies, corporations, governments and so on, with motives ranging from profiting from sustainable use through to scientific research and good citizenship images. Panayotou (1994b) suggests that corporations in developed countries could be given credit for buying into such tradable rights, e.g. through relaxations on domestic regulatory obligations. Measure against the *status quo* this obviously has the disadvantage of 'trading' environmental quality between developed and developing country economies, a problem that has brought criticism on joint implementation proposals already. Nonetheless, the approach could be utilized in the event of tighter developed country restrictions being contemplated.

The incentives that are required to conserve biological resources and diversity at the local level usually require commensurate policies at the national level. A *national or regional conservation strategy* can be an effective means of reviewing such policies, and of determining what shifts are required to achieve national objectives for biodiversity conservation. The following steps are a necessary component of such a strategy (McNeely 1993).

1. Quantify and bring to the attention of policy-makers the many economic and financial benefits of integrating rural development activities with conservation of biological resources and diversity.
2. Identify both conflicts and potential for co-operation between the various activities of agriculture, fisheries, forestry, conservation and rehabilitation of degraded lands.
3. Formulate legislation consonant with the socioeconomic patterns of the target group and the natural resources being utilized, both to institute a system of penalties and rewards and to ensure that incentives carry the power of law.
4. Review policies and legislation in other sectors for possible applications to conservation of biodiversity and community involvement in such work.
5. Devise effective incentives to accelerate integrated development to close any gap between what the

individual sees as an investment benefit and what the government considers to be in the national interest.

6. Establish new administrative structures for managing biological resources. While those resources contained within strictly protected areas are usually government controlled (in theory), biological resources in buffer zones, coastal areas, national forests and communal areas are often 'open access' resources and need to be brought into some form of management regime.
7. Develop the capacity of local communities to participate in conservation efforts so as to ensure that these measures are more likely to yield immediate and real benefits to local people.

12.7.5 Incentives, property rights and the distribution of assets

Given the emerging consensus amongst community and systems ecologists about system structure and functioning, the major implication of an economic approach to the problem of biodiversity loss is that it should be concerned less with the preservation of the status quo than with the maintenance of sufficient biodiversity to assure the resilience of ecosystems delivering services of value to humanity. Much of the non-economic literature on biodiversity loss has tended to focus on the preservation of species now threatened with extinction due to the loss of habitat. But if we are concerned with the sustainability of resource use, then we are generally concerned with something rather different. Species loss is important primarily because it threatens the resilience of the ecological systems on which humankind collectively depends.

Since the non-existence of markets is a major cause of the divergence between the private and social cost of species deletion, and since the non-existence of markets reflects the incompleteness of property rights, it is not surprising that one option for ensuring against excessive species depletion is the allocation of property rights in order to create markets. This is particularly appropriate where the problem is one of local depletion as a consequence of some unidirectional externality. Though biodiversity in general is in the nature of a public good, many species and even more local populations are both exclusive and rival in consumption. Similarly, though many aspects of the biosphere are in the nature of public goods, many ecosystems and ecosystem services are similarly exclusive and rival in consumption. If it is possible to generate markets in these, it may be possible to eliminate one source of discrepancy between private and social cost. This is, of course, subject to the usual restrictions concerning the numbers of people party to an externality, and the costs of negotiation. It should also be borne in mind that the word 'market' can mean something

much more general than the locus of price-based transactions. It includes, for example, all those institutions that facilitate the negotiation between the parties affected by some action (Dasgupta 1991; Dasgupta and Mäler 1991).

There are innumerable potential candidates for a solution involving the creation of markets through the allocation of rights, some of which have been discussed above. In each case the optimal solution has to take into account not only the incentive effects of the proposed allocation of property rights, but also whether they meet the wider objectives of society. Property rights evolve in different circumstances to meet a range of institutional and cultural conditions and a specific set of social objectives. Hence one is interested in asking whether there exists a modification that will prevent the over-utilization of environmental resources, either (a) without conflicting with these original conditions or objectives, or (b) by meeting the needs of changes in both institutions and conditions.

This often depends on the distributional impact of any change in the structure of property rights. We have repeatedly drawn attention to the importance of both market and non-market income in the private valuation of resources, and have remarked on the potential for income effects to dominate the private valuation of resources, the rate at which the future costs of present activity are discounted, and the amount of information acquired in the decision-making process. The distribution of assets in any given case will have considerable bearing on the distribution of market and non-market income, and so on the private valuation of resources. The point here is that the reallocation of property rights implies the redistribution of assets, since no allocation takes place in a vacuum. Indeed, in our earlier discussion of the effectiveness of incentives to local producers, we have assumed that this will depend on a redistribution of assets in favour of the poorer resource users.

Similarly, the indirect threat to biodiversity of high levels of indebtedness in the low-income countries is what lies behind various proposals to reduce the debt burden of those countries, including the proposals to swap debt for 'nature' – some of which have been reviewed in Chapter 12.5 for their implicit valuation of the resources. At the micro-economic level, there is a further reason to be concerned about the level and distribution of income apart from its effect on the information sought in the decision-making process and the rate at which future costs are discounted. At very low levels of income the probability that the income effects in price changes will be perverse rises. In other words, an increase in the private cost of some environmental resource may lead to an increase in its usage rather than a decrease. As a result, the goals of a price policy designed to promote biodiversity conservation by reducing pressure on ecosystems may be compromised by the effects of that policy on income (Perrings 1991). This is why income transfers are a necessary part of instruments used to change the incentives to private resource users.

A common characteristic of many ecosystems is that resources are non-exclusive in their use: they are in the nature of local (congestible) public goods. Hence markets in the resources will not tend to develop naturally. Property rights can still be allocated to environmental public goods, but in this case they should be restricted to usufructual or user rights. Harvesting quotas, emission permits and the development rights discussed earlier in this chapter are all examples of such rights.

Given the uncertainty associated with the future environmental effects of increasing levels of use of these resources, and the potential for 'overshooting' ecological thresholds and the irreversibility of the effects of overshooting, the best means of assuring the ecological sustainability of economic activity lies in the application of safe minimum standards of environmental access. It has been argued that the rational response to the irreversibility of environmental effects is to slow down the rate of environmental exploitation (Henry 1974; Miller 1981). Where the existence of thresholds means that unknown irreversible effects may be catastrophic, the same models indicate that it is prudent not just to slow down the rate of exploitation where this approaches critical thresholds, but to stop it.

Notice, though, that even though the application of safe minimum standards of environmental access appears to limit the scope of the market in conserving biodiversity, it actually heightens the need for the economic valuation of biological resources. The role of valuation in this case is twofold: to help in the identification of the right level of biodiversity protection and to help establish the financial incentive needed to secure that level of protection. Since any level of an environmental protection involves some cost, what is needed is an estimate of the benefits to society of protection at different levels. Similarly, since any level of protection implies a corresponding level of demand for environmental resource, what is needed is an estimate of the resource 'price' that will generate such a level of demand.

A special set of problems surrounds the regulation of access to resources in which there is no clear central authority, sometimes referred to as the global commons. In reality, access to every public good involves a political process, in the course of which users cede rights to some decision-making regulatory authority. However, this is most obviously a difficulty in the case of ecological services that extend across a number of juridical boundaries, such as, for example, the upper atmosphere. Global biodiversity is in the same category. A considerable amount of work has now been done on the strategic behaviour of participants to international environmental negotiations, and the conditions necessary to achieve a co-operative outcome (Barrett 1990, 1994; Dasgupta and Mäler 1991). Work on the strategic behaviour of parties to international negotiations over common property resources, and the more familiar compensation principle, suggest the importance of transfers

as instruments of international environmental policy and this is in fact the basis of the Global Environment Facility.

The critical questions from an economic policy perspective concern the distribution of the benefits of biodiversity conservation between individual users of biological resources, nation states, regional groupings and the international community. It is the fact that the private and social costs of biodiversity depletion differ that creates the problem of excessive biodiversity loss in the first instance. But, as Barrett (1994) shows, it is the distribution of the social costs of depletion that determines how effectively the problem may be addressed. The link that is now being emphasized between functional diversity and ecological resilience is significant precisely because of its implications for the distribution of the social costs of biodiversity depletion. If the main implications of biodiversity depletion lie in the genetic information losses associated with species or population deletion, then it follows that the main social costs of biodiversity loss are indeed global. However, if the main implications of biodiversity depletion lie in the loss of ecosystem resilience, then the main social costs of biodiversity loss will be ecosystem-specific. That is, to a large extent they will manifest themselves in the same physical system as that in which the losses were incurred.

This point seems to us to be of considerable importance. If it is understood that a large part of the social costs of biodiversity are local, not only is the problem easier to address at a national level, but the relative value of the transfers needed to induce international co-operation is also reduced. Species deletion at private hands may still involve both information and insurance costs that are incurred by the global community, but if the main external costs of private actions leading to loss of functional diversity accrues to other users of the same ecosystem, the optimal policy response is a local one.

12.7.6 Concluding remarks

We conclude by restating what seem to be the most important observations on the link between valuation, policy and the conservation of biodiversity:

- The allocation of biological resources on the basis of current market signals is **inefficient and inequitable**. It leads to losses in social welfare. Moreover, these losses are distributed in a way that bears most heavily on both the poorer members of this generation and all members of future generations. An appropriate strategy for biodiversity conservation should address both the efficiency and equity issues. Valuation is an essential element of this.
- The valuation of biological resources provides a means of (a) quantifying the costs of market and policy failure, (b) testing its sensitivity to assumptions

made about the distribution of income and assets and the weight given to consumption by members of future generations, (c) identifying where markets might be reformed to remove the current sources of bias, (d) showing, where it is not possible to reform markets, how governments might intervene to correct the signals to private resource users, and (e) indicating how and where economic activity can be constrained so as to protect biological resources that are important for maintaining the options open to future generations.

- Efficiency and equity both require the development of effective **institutions** and **incentives** that will (a) confront resource users with the full social cost of their behaviour, and (b) enable those who invest in conservation to appropriate the benefits.
- Traditional approaches to protected areas have sometimes worked against the interests of local populations by removing traditional rights of access to the resources in protected areas and the benefits of that access, thereby taking responsibility for management of the area away from local people.
- To be effective in an evolving ecological-economic systems, institutions need to be **adaptive**, i.e. able to respond to environmental feedbacks before those effects challenge the resilience of the entire resource base, and the economic activity that depends on it.
- Institutions need to safeguard the resilience of ecosystems by safeguarding the biological resources which support that resilience. It is necessary to **bound economic activity to minimize the risk of irreversible damage** to ecosystems on which human activity depends. The rational response to the irreversibility of environmental consequences of economic activity is to slow down that activity. Where the existence of thresholds means that unknown irreversible effects may be catastrophic, the rational response is to stop it.
- Preserving biological resources through nature reserves and other protected areas may be an important short-term step where biological resources are under immediate threat. But it is not feasible to protect critical ecological systems by excluding human users of wild resources.

Measures for Conservation of Biodiversity and Sustainable Use of its Components

K. MILLER, M.H. ALLEGRETTI, N. JOHNSON AND B. JONSSON

Lead Authors:

K. Miller, N. Johnson (Chapter 13.1); N. Johnson (Chapter 13.2); N. Johnson, B. Jonsson (Chapter 13.3); R. Hobbs, E. Lleras (Chapter 13.4); M. Wells (Chapter 13.5); C. de Klemm (Chapter 13.6); K. Miller (Chapter 13.7)

Contributors:

M. Allegretti, M. Altieri, C.V. Barber, F. Berkes, R.J.H. Beverton, A. Bjordal, T. Boyle, S. Bragdon, J. Caldecott, R.A. Caulfield, H. Ceballos-Lascurain, A.L. Decicco, S.R. Edwards, D. Farrier, A.H. Ghosh, A.N. Gillison, E. Gómez, L.P. Hansen, V.H. Heywood, K. Hindar, M. Iwanaga, D. Janzen, K. Kangwana, A. Kothari, R. Langvatn, S.M. Lanou, K. MacKinnon, P. Maitland, A. Mariante, J. Paine, G. Power, R.B. Primack, F.E. Putz, W.V. Reid, C. Shine, S. Singh, S. Stuart, T. Whitten, H.G. Wilkes

CONTENTS

Executive Summary	919		
13.0 Introduction	923		
13.1 A framework for managing biodiversity	923		
13.1.1 Introduction	923		
13.1.2 Context for biodiversity management	925		
13.1.3 Methods and tools for biodiversity management	925		
13.1.4 Approaches for managing biodiversity in a complex world	927		
13.1.4.1 Strategic planning	927		
13.1.4.2 Bioregional and ecosystem management programmes	929		
13.1.4.3 Adaptive management	931		
13.1.5 Conclusion	931		
References	931		
13.2 Defining priorities for conservation and sustainable use	932		
13.2.1 Introduction	932		
13.2.2 Genetically based methods for establishing priorities	933		
13.2.3 Species-based methods for establishing priorities	934		
13.2.4 Ecosystem-based methods for establishing priorities	936		
13.2.5 Integrative approaches for establishing priorities	937		
13.2.6 Experience in setting geographically-based priorities	938		
13.2.7 Principles for geographic priority setting	939		
13.2.8 Conclusion	940		
References	941		
13.3 Measures for sustainable use of biodiversity in natural resource management	943		
13.3.1 Introduction	943		
13.3.2 Managing biodiversity in agriculture	943		
13.3.2.1 Managing biodiversity in traditional agriculture	944		
13.3.2.2 Managing biodiversity in modern agriculture	948		
13.3.2.3 Managing agriculture impacts on natural resources	950		
13.3.3 Managing biodiversity in forestry	952		
13.3.3.1 Managing biodiversity in traditional forestry	952		
13.3.3.2 Managing biodiversity in commercial forestry	954		
13.3.3.2.1 Measures for the sustainable use and management of forest genetic resources	954		
13.3.3.2.2 Minimizing the impacts of forestry operations on biodiversity	956		
13.3.3.2.3 Biodiversity inventory and monitoring	958		
13.3.4 Managing biodiversity in fisheries	960		
13.3.4.1 Managing biodiversity in traditional fisheries	960		
13.3.4.2 Managing biodiversity in small-scale fisheries	962		
13.3.4.3 Managing biodiversity in large-scale fisheries	963		
13.3.4.4 Newly evolving practices in large-scale fisheries	964		
13.3.4.5 Managing biodiversity in aquaculture	965		
13.3.5 Managing wild flora and fauna	966		
13.3.5.1 Wildlife management	966		
13.3.5.2 International commerce in wild species	967		
13.3.5.3 Incentives for managing wild populations sustainably	968		
13.3.6 Biodiversity prospecting	969		
13.3.7 Managing impacts of tourism on biodiversity	970		
13.3.8 Managing impacts of urbanization and infrastructure on biodiversity	971		
13.3.8.1 Conserving biodiversity in urban areas	971		
13.3.8.1.1 Habitat types	971		
13.3.8.1.2 Species diversity in urban habitats	972		
13.3.8.1.3 Actions to conserve urban biodiversity	972		
13.3.8.2 Managing the impacts of infrastructure on biodiversity	973		
13.3.9 Conclusion	973		
References	974		
13.4 Protecting and restoring ecosystems, species, populations and genetic diversity	981		
13.4.1 Introduction	981		
13.4.2 Protecting ecosystems	982		
13.4.2.1 Protected areas	982		
13.4.2.1.1 Protected area classification, size, and distribution	982		
13.4.2.1.2 Managing biodiversity in protected areas	986		

13.4.2.1.3	Defining management objectives	987	13.6 Legal measures for sustainable use and protection of biodiversity	1036
13.4.2.1.4	Effectiveness of protected areas for maintaining biodiversity	990	13.6.1	Introduction
13.4.2.2	Managing corridors and natural habitat fragments	990	13.6.2	Customary and traditional legal measures
13.4.2.2.1	Response of ecosystems to fragmentation	990	13.6.2.1	The nature of customary law
13.4.2.2.2	Corridors in fragmented landscapes	992	13.6.2.2	Examples of customary law and biodiversity
13.4.2.2.3	Protection and management of fragments	993	13.6.2.3	Customary law in transition
13.4.2.3	Maintaining ecosystem functions and processes	993	13.6.3	National legislation
13.4.3	Protecting species, populations and genetic resources	994	13.6.3.1	Regulatory measures
13.4.3.1	Threatened and endangered species classifications and species management and recovery plans	995	13.6.3.1.1	Species-orientated legal measures
13.4.3.1.1	Threatened and endangered species classifications	995	13.6.3.1.2	Regulating use of protected areas
13.4.3.1.2	Management plans	995	13.6.3.1.3	Other area-based legal conservation actions
13.4.3.1.3	Recovery plans	997	13.6.3.1.4	Land-use planning legislation
13.4.3.1.4	IUCN Species Survival Commission Action Plans	997	13.6.3.1.5	Nature parks and protected landscapes
13.4.3.2	<i>In situ</i> conservation of species, populations and genetic resources	998	13.6.3.1.6	Legal protection of representative habitat types
13.4.3.3	<i>Ex situ</i> strategies	1000	13.6.3.1.7	Regulating processes and activities detrimental to biodiversity
13.4.3.3.1	Botanical gardens	1000	13.6.3.1.8	Regulating access to genetic resources
13.4.3.3.2	Zoos and aquaria	1001	13.6.3.2	Non-regulatory methods
13.4.3.3.3	Gene banks	1002	13.6.3.2.1	Financial incentives
13.4.3.3.4	<i>Ex situ</i> technologies	1003	13.6.3.2.2	Covenants
13.4.4	Restoration and rehabilitation of species, populations and ecosystems	1004	13.6.3.2.3	Easements
13.4.4.1	Restoration of species and populations	1004	13.6.3.2.4	Management agreements
13.4.4.2	Ecosystem and landscape restoration	1007	13.6.3.3	Combining regulatory and voluntary measures
13.4.5	Conclusion	1008	13.6.3.4	Environmental impact assessment and other legal institutions and procedures for conserving biodiversity

EXECUTIVE SUMMARY

A growing number of countries are now party to the 1992 Convention on Biological Diversity and are taking steps to implement various articles of the treaty. An up-to-date assessment of a wide range of technical, social, economic and legal approaches available to achieve conservation and sustainable use, therefore, provides a timely contribution to conservation planning efforts around the world. Section 13 addresses specific methods available for the conservation, restoration and sustainable use of biodiversity and its components at the ecosystem, species and genetic levels. It also indicates new directions for improving the efficacy of current methods and strategies. Within the scope of this Section are approaches to help:

- plan and co-ordinate conservation efforts;
- sustainably use biodiversity within management systems such as forestry, fisheries and agriculture;
- protect and restore ecosystem, species and genetic diversity using a variety of in situ and ex situ methods;
- equitably share the benefits of biodiversity through social and economic instruments;
- provide a legal basis for conservation and sustainable use activities; and
- build human and institutional capacity to integrate measures at bioregional scales.

(13.1) The first chapter of this Section addresses the usefulness of developing a conceptual framework within which to organize the wide range of responses needed to conserve biodiversity and use it sustainably. In most places, biodiversity conservation has suffered from piecemeal and uncoordinated actions. The Convention on Biological Diversity calls for the development of intersectoral national biodiversity strategies and action plans (Article 6), and provides an opportunity to develop comprehensive and co-ordinated strategies for the conservation and sustainable use of biodiversity.

A conceptual framework should recognize that a range of public and private actors have roles and responsibilities to conserve living resources and use them sustainably, and that many different types of actions will be necessary to successfully maintain biodiversity. Such a framework can help integrate different methods and sectors involving

components as varied as: seed banks; protected areas; technical measures in forestry, agriculture and aquaculture; botanical gardens; on-farm conservation areas; legislation; and a variety of social, economic and political factors. Because of the complexity and uncertainty associated with the management of biodiversity, the use of strategic planning, adaptive management techniques, and bioregional and ecosystem management approaches should frame the choice of tools and techniques.

(13.2) Deciding which species and habitats have precedence in the allocation of limited financial, human and institutional resources is one of the most difficult aspects of conservation planning in the 1990s. Many methods of setting geographic priorities for a wide range of conservation objectives have been developed over the last decade. These include widely publicized schemes to identify global priorities on the basis of species richness and endemism at the country level (e.g. megadiversity countries), the regional level (biodiversity ‘hotspots’), and the site level (e.g. endemic bird areas).

While these approaches provide limited guidance to international funders, setting priorities for the conservation and sustainable use of biodiversity at national and local levels will have more impact. Relatively few countries, however, have established clearly defined priorities that are actively used to guide biodiversity management activities or to direct government and donor resources. Where such priority-setting has occurred, the efforts have often been isolated from the policy process. They have lacked participation from key constituencies and have ignored social, economic, institutional and other factors that play a major role in conservation decisions. New approaches are emerging that are more participatory, integrate a wider range of biological and non-biological factors relevant to conservation threats and opportunities, and are more closely linked to clear conservation objectives and planning processes. While the effectiveness of these methods is not yet certain, growing genetic, species and habitat loss will leave fewer conservation options in coming decades. Thus, priorities set during the next decade are likely to influence conservation and sustainable use activities for decades to come.

(13.3) The next part of the Section assesses methods available to conserve biodiversity and use it sustainably in the context of natural resource management involving

agriculture, fisheries, forestry, tourism and biodiversity prospecting, among other activities. Some components of biodiversity owe their existence to human influence and manipulation; yet human use of resources has often led to simplification of ecological systems and reduction in biodiversity. Our ability to maintain biodiversity, therefore, is dependent upon finding methods to manage and use biodiversity sustainably in systems where the production of goods and services for human consumption is the principal objective.

Areas that practise traditional forms of agriculture, particularly in developing countries, are the largest repositories of crop and livestock genetic diversity. Much of the genetic diversity associated with traditional systems, however, is disappearing as large-scale, modern agricultural systems become more prevalent. Modern agriculture has offered tremendous gains in productivity through technological innovation and the widespread adoption of uniform, high-yielding varieties. Future gains in productivity will depend on improved management of genetic resources in time (e.g. gene banks) and space (e.g. crop-variety mosaics).

Genetic vulnerability for many of the world's most important food crops and animals appears to be growing. This is apparent even though we have an incomplete understanding of the magnitude of potential future losses in crop productivity caused by the narrowing of the genetic base for breeding. To meet the demands of a growing world population and simultaneously maintain biodiversity requires measures that:

1. conserve genetic diversity in existing domesticated plant and animal varieties;
2. identify and conserve wild species that, along with their genetic diversity and habitats, can improve agricultural productivity and adaptability in the face of environmental change; and
3. minimize the adverse impacts of agricultural practices on other ecosystems.

Traditional approaches to forest and fisheries management have also – intentionally or unintentionally – contributed to the maintenance of biodiversity. As in agriculture, however, traditional practices are disappearing rapidly. The intensification of forestry and fisheries management has led to dramatic increases in yield. This, in its turn, has caused significant interventions in natural disturbance regimes and species composition, and consequent reductions in biodiversity for many forestry and fisheries production areas. Forestry practices that mimic natural disturbance regimes such as fire, wind blow-downs, and pathogen outbreaks appear to offer the best

opportunities for maintaining biodiversity associated with forest ecosystems.

In fisheries, better monitoring of fish stocks and more selective fish capture methods have been shown to offer considerable hope for increasing the sustainability of harvest and the conservation of marine biodiversity. Social and economic measures, however, may be much more important than technical measures for ensuring sustainable use. For example, the assignment or recognition of clearly defined property rights and tenure systems is vital to sustainable use behaviour in forestry and fisheries (see also 13.5).

(13.4) Even as methods are being developed to use biodiversity sustainably, approaches are also being explored to protect ecosystems, species and genetic diversity – either in place (*in situ* methods can be used at all biological levels) or in specially designed facilities away from natural habitats (*ex situ* methods can be used for species and genetic diversity). These approaches are, in essence, the means by which we can protect biodiversity against the failure of the sustainable use measures described above (13.3).

The most effective way to conserve biodiversity, by almost any reckoning, is to prevent the conversion or degradation of habitat. The world's 10 000 protected areas have figured prominently in biodiversity conservation efforts. Reasonably accurate data on the number and size of protected areas are available for most countries, and gaps in the representation of major ecosystem types by country and biome are generally well understood. More specific information, however, on the effectiveness of protected areas in conserving elements of biodiversity is generally not available. For example, information on the biodiversity that is resident within protected areas, especially at the genetic level, even for plants and vertebrates, is inadequate for the vast majority of protected areas.

Protected areas, particularly in developing countries, have often yielded few economic benefits and instead have imposed substantial costs on local people. This has led to severe conflicts between conservation and economic development goals. The potential of many innovative protected area projects designed to integrate conservation and development objectives has been hampered by a number of factors. Among them are limited investment, inadequate use of the latest ecological and social science techniques, minimal attention to monitoring, and neglect of larger economic and sectoral policies. Recent assessments suggest that:

- local people must be involved in all phases of project design, implementation and evaluation;
- project objectives must be clearly defined;
- a wide array of human and organizational resources is needed across sectoral and disciplinary boundaries;
- baseline ecological, biodiversity, social and economic conditions must be characterized,

monitored and evaluated over time; and

- economic incentives for conservation should be designed with special attention paid to who benefits, how, and by how much.

Protected areas, because of constraints on size, representativeness and management effectiveness, must be augmented by protective measures elsewhere. Fragmentation of natural ecosystems is generally seen as one of the most critical threats to biodiversity world-wide. Protecting individual habitat fragments and natural habitat corridors within a matrix of more intensive human uses of the landscape (where sustainable use methods are employed, as described in 13.3) are likely to be important factors in the persistence of native biodiversity in many areas.

A wide array of techniques to conserve individual species, populations and genes must complement conservation efforts made at the landscape and ecosystem levels. *In situ* measures, such as habitat protection or in-field conservation, are generally more effective than *ex situ* conservation techniques. *In situ* management, however, faces two major limitations: (1) a lack of information on the conservation status and habitat needs of individual species, and (2) the considerable economic or opportunity costs for conserving individual species or populations.

A growing range of *ex situ* technologies associated with gene banks, zoos, botanical gardens and aquaria has rapidly expanded our capacity to preserve species and genetic diversity. However, none of the *ex situ* technologies is fail-proof. Depending on the technology, they are vulnerable to pests and disease, physical damage to facilities from natural causes (e.g. fires, floods, storms, etc.) and human events (e.g. war, economic decline, policy change, etc.). World-wide, for example, genebanks contain over 4 million unique samples of seeds, but a high percentage of these accessions have probably died because of poor maintenance and a lack of adequate storage facilities.

One way to compensate for the limitations of *ex situ* conservation measures is to deploy measures to restore and rehabilitate natural populations and ecosystems. A small number of endangered species (mostly mammals and plants) have been reintroduced successfully to natural habitats, sometimes after many years of survival only in captivity. The success rate, however, has been low. The more complex challenge of restoration ecology (restoring ecosystem processes and biological communities) is in its infancy and consists largely of *ad hoc* responses to particular problems. Clearer enunciation of the goals, techniques and theoretical framework of restoration ecology will lead to its inclusion as a major tool in biodiversity conservation.

(13.5) This chapter analyses the use of socioeconomic tools to manage biodiversity more effectively. Linking the benefits of biodiversity conservation to local peoples and

other interests that make decisions impacting the health of species and ecosystems is a key, often indispensable, component of successful conservation and sustainable use strategies. The use of socioeconomic tools in support of biodiversity management is a relatively recent phenomenon. The limited assessments of their effectiveness suggest that recognizing the value of local and indigenous knowledge, and improving local participation in planning, implementation and monitoring, are often keys to successful biodiversity management programmes.

Locally targeted economic incentives are also important. These can be used to increase the value people in developed and developing countries attach to biodiversity, and therefore the likelihood that they will embrace sustainable use and conservation practices. Relatively little, however, is known about the level at which economic incentives become effective under various conditions. For example, debate over the potential of non-timber forest products and ecotourism illustrates the difficulties in choosing appropriate local economic incentives. Clearly, however, local economic incentives are vital and more focused research is needed to provide a more realistic assessment of their role and importance.

(13.6) Incentives alone, however, will not always be enough to conserve and sustainably use biodiversity. Human activities will have to be regulated in some situations if biodiversity conservation is a societal goal. A range of legal and institutional tools can create economic incentives to conserve biodiversity directly and influence its management through regulatory action. Customary and traditional legal methods have served to promote the conservation and sustainable use of biodiversity, some of which have worked effectively for centuries in parts of Asia and Africa. These can remain a vital part of conservation and sustainable use strategies if they are not entirely supplanted by modern legal systems.

Modern legal and institutional tools for the protection and sustainable use of species and ecosystems have moved from a primary focus on regulatory measures to increased emphasis on encouraging voluntary systems based on contracts and incentives. Legal strategies have been stimulated by the provisions of the Convention on Biological Diversity, but they are only now beginning to address regulatory and incentive systems for controlling access to and distributing benefits from the sustainable use of genetic resources. One of the most important institutional changes required to enhance incentives and improve the acceptance of regulation is to establish an appropriate balance between national and local control over resources.

(13.7) Biodiversity management calls for higher levels of co-operation and co-ordination than are required in traditional sectoral approaches to natural resource management. In one way or another, biodiversity is an

important part of forestry, fisheries, agriculture, tourism and coastal zone management; and in turn, its conservation is affected by many other sectors. Integration of conservation and sustainable use measures is generally constrained by a lack of human, institutional and financial capacities to implement and co-ordinate appropriate method combinations in the field. Little is known about the existing and additional capacity required in each of these areas to manage biodiversity adequately on a global basis. What is known suggests that substantial additional capacity is needed.

13.0 Introduction

Section 13 considers steps for conserving and sustainably using biodiversity, particularly in light of the articles in the Convention on Biological Diversity. Building on earlier sections that analyse how and why biodiversity is being lost (Sections 4, 5, 6, 11 and 12 in particular), Section 13 offers a review of the responses available to sustainably use and conserve ecosystems, species, populations, and genetic diversity. The section assesses a wide range of technical methods and social, economic, and legal measures relevant to the use and protection of the Earth's biotic wealth. The approaches described herein are representative, but not inclusive, of the thousands of approaches being used around the world. In the right combination, these methods can provide the opportunity to effectively counter threats to biodiversity noted in previous chapters. Within the broader context of sustainable development, such approaches are an essential basis for improving the human future.

Chapter 13.1 discusses the benefits of developing a conceptual framework to relate the wide array of methods necessary to sustainably use, conserve, and restore biodiversity at the national level. Several sets of issues are presented that relate to the interaction and effectiveness of conservation and sustainable use measures. These issues include the importance of:

1. integrating different types of approaches to ensure that the widest possible range of biodiversity and its components are sustainably used and conserved;
2. recognizing that the conservation and sustainable use of biodiversity are heavily influenced by social, cultural, economic and political attitudes and conditions; and
3. encouraging policy and institutional co-operation and co-ordination to achieve conservation goals and objectives.

Recognizing the complexity and uncertainty associated with biodiversity and its sustainable use and conservation, the use of strategic planning, adaptive management techniques and bioregional/ecosystem management approaches are emphasized.

Chapter 13.2 presents an overview of methods for setting priorities for biodiversity conservation, with an emphasis on their application at national levels. Deciding which species and habitats have precedence in the allocation of limited financial, human and institutional resources is a difficult but inevitable aspect of conservation planning in the 1990s. This chapter presents various types of approaches to priority setting, including examples of priority-setting efforts in practice.

Chapter 13.3 presents methods that maintain or facilitate the sustainable use of biodiversity within the context of human uses and management of natural resources,

including agriculture, forestry, fisheries, wild flora and fauna harvesting, biodiversity prospecting, and tourism. These methods are directed toward resource management systems in which the primary objectives are to use natural resources for human consumption and benefit, not to preserve biodiversity *per se*.

Chapter 13.4, on the other hand, discusses aspects of management systems where the conservation or restoration of biodiversity is a principle objective. Approaches are presented for a range of conservation systems including, among others, protected areas and natural habitat management, restoration ecology, zoos, botanical gardens, museums, and germplasm storage and maintenance facilities. These approaches are, in a sense, insurance against the limitations of the sustainable use methods presented in the previous chapter.

Whereas the measures presented in Chapters 13.2 to 13.4 are largely technical, Chapter 13.5 examines ways to address local social and economic issues relevant to sustainable use and conservation efforts. These approaches include using various types of social strategies such as greater use of local and indigenous knowledge, and improved participation in planning and management, and locally targeted economic incentives such as markets for non-timber forest products and ecotourism to create greater social and economic benefits from biodiversity. Such measures can be critical to the success of the technical measures previously discussed.

Chapter 13.6 considers legal measures that can be used to regulate activities with adverse impacts on biodiversity and to create the legal basis for implementing technical, social and economic methods to sustainably use and conserve biodiversity. Legal tools are considered in the context of both traditional legal systems and modern legal systems used at national and international levels.

Finally, Chapter 13.7 assesses human, institutional, infrastructure and financial capacities to carry out integrated and comprehensive biodiversity management programmes.

13.1 A framework for managing biodiversity

13.1.1 Introduction

The goal of biodiversity management is to 'strike the optimal balance between conserving the diversity of nature and advancing human sustainable living'. To effect sustainable development, governments, citizens, international organizations and businesses will have to co-operate in finding ways to support the essential processes of the planet, an effort that depends on maintaining biological diversity. 'Maintaining as much of the latter as possible has to be a social goal, and a large component of strategies for sustainability' (Holdgate 1994).

'Biodiversity management' is the human effort to plan and implement a set of approaches to:

1. protect and sustainably use biodiversity and biological resources, and ensure adequate sharing of benefits therefrom;
2. develop the human, financial, infrastructural and institutional capacity to address these objectives; and
3. establish the institutional arrangements necessary to foster the required co-operation and action by private and public sector interests.

Biodiversity management, as used here, seeks to maintain biodiversity for its associated material, social, cultural, spiritual and ecosystem values (see Section 12). It also includes the full range of management activities, from the preservation of species, their genetic traits, and the array of habitats and landscapes, through the restoration of ecosystems and the harvesting of plant, animal and microbial resources for human need, to the generation and distribution of benefits.

For the sake of consistency with the Convention on Biological Diversity, Section 13 will employ the term ‘conservation’ in its most restricted form to mean ‘protection’, leaving use and the sharing of benefits to be stated separately, as appropriate. This represents an important departure from the universally agreed-upon and adopted terminology of the *World Conservation Strategy*, where conservation was defined to embrace all three dimensions of protection, sustainable use and benefit sharing (IUCN/WWF/UNEP 1980).

Previous sections of this report have demonstrated that biodiversity is extraordinarily complex; that is, there are numerous elements involved and myriad interrelationships and interdependencies among them, many of which are poorly understood. Achieving the goal of balanced conservation, sustainable use and benefit sharing under these circumstances requires careful organization and focus of human enterprise.

The causes of biodiversity loss and impoverishment have been reviewed earlier in this assessment. The more obvious forces include various forms of habitat loss, pollution, over-exploitation and the introduction of invasive species (see Section 11). Behind these forces lie more complex causes that are often found within the very policies, laws and administrative arrangements established by governments and people. The Global Biodiversity Strategy (WRI/IUCN/UNEP 1992) identifies six fundamental causes of biodiversity loss (see Box 13.1-1). Actions taken to address immediate threats to biodiversity will have little effect unless they are supported by efforts to address the underlying causes that sustain the over-exploitation of species and destruction of habitats (see Section 12).

Success at meeting the objectives of biodiversity management – namely, protection, sustainable use, and benefit sharing – depends upon two things. First, policy-makers and managers need an adequate understanding of the social, political, economic and cultural context within

Box 13.1-1: Six fundamental causes of biodiversity loss.

1. Unsustainably high rates of human population growth and natural resource consumption.
2. Steadily narrowing spectrum of traded products from agriculture and forestry, and introduction of exotic species associated with agriculture, forestry and fisheries.
3. Economic systems and policies that fail to value the environment and its resources.
4. Inequity in ownership and access to natural resources, including the benefits from use and conservation of biodiversity.
5. Inadequate knowledge and inefficient use of information.
6. Legal and institutional systems that promote unsustainable exploitation.

Source: WRI/IUCN/UNEP (1992).

which these biodiversity management objectives are pursued. Second, they need to select tools and methods that show promise in meeting those ends.

Section 13 considers the context within which biodiversity management takes place and explores the various tools and methods presently available for taking action to meet biodiversity management objectives. This chapter presents a framework for action, consisting of three components:

1. the **context** for biodiversity management;
2. the **methods and tools** for action to manage biodiversity; and
3. **approaches** for biodiversity management programmes in a complex and uncertain world, including the preparation of strategies and action plans to integrate the planning and implementation of these methods and tools.

Chapters 13.2 to 13.6 assess the tools, methods and strategies available to manage biodiversity. The final chapter (13.7) closes Section 13 with a fifth component of the framework introduced in Chapter 13.1: the development of the human, institutional, infrastructural and financial **capacity** to manage biodiversity.

13.1.2 Context for biodiversity management

The content of a nation's biodiversity policies and plans will affect decisions on the choice of methods and tools that best fit that country's particular cultural, historical, social, economic and ecological reality.

The success of a biodiversity action programme will depend on being able to pull the components and disciplines together into an integrated approach. But, no matter how biologically or technically sound, action plans often fail where they ignore the vital role and influence of public awareness levels, fail to incorporate local and traditional knowledge, fail to address issues of poverty and economic development, and fail to consider contemporary policy issues.

The choice of methods and tools for biodiversity management will depend upon the given state of awareness and understanding in the general population, in the leadership of private and public agencies, and in government circles. Where awareness is low, initial activities and investments may need to focus on preparing and distributing information, sponsoring special events and establishing demonstration areas. Alternatively, where awareness is high, action may proceed directly to strengthen protected areas, develop biodiversity prospecting programmes or shift to sustainable forestry practices.

Local knowledge of rural and indigenous peoples can provide the management of biodiversity with long-term experience and observation. While modern agriculture, forestry and fisheries are vital to meet present and future demands for food and fibre, their potential to become more sustainable, and to preserve options for new opportunities such as pharmaceutical prospecting, can be enhanced by incorporating lessons from the past.

The best approach for biodiversity management will also vary considerably with a country's level of economic development. Obviously, a country that has a high proportion of its people living in poverty will face different priorities for the use of public funds from one with an affluent population. The competition for land and resources may be particularly high in a developing country, leading to conflict. For example, is a forest to be cleared for food production, or is it to be retained in its wild state for ecotourism, biodiversity prospecting and other uses? Which alternative can best offer benefits to support local people?

The effectiveness of biodiversity management also depends on the institutional and policy environment within which actions are taken. Many governments have negotiated internationally agreed treaties and conventions that limit and orientate the conservation and use of natural resources, including biodiversity. Nationally, policies may promote positive or negative actions for biodiversity conservation and use. All too often they stimulate –

intentionally or unintentionally – the conversion of important habitats, unsustainable use of biological resources, and pollution and environmental degradation.

Hence, the planning and implementation of biodiversity management may begin within a context that features a range of conflicts in the international and national arena. Obligations under international agreements may require action to reform national policies and develop positive responses. Alternatively, international agreements that may hinder the efforts of some countries to manage their biodiversity sustainably may require reforms or more flexible interpretation. For example, the ban on ivory trade supports conservation in East African countries, but challenges rural economic development and conservation in southern African countries.

Biodiversity management requires interdisciplinary skills. Biologists, economists, anthropologists, engineers, foresters, agriculturalists, marine scientists and an array of community organizers, field managers and administrators are needed to address the multiple dimensions involved.

Flexibility must be used to set the appropriate geographic extent of the area to be managed. Populations, species, habitats and ecosystems each have their own geographic ranges – boundaries that are typically distinct from the administrative and sectoral boundaries of local and national public agencies, private lands and communal territories.

Biodiversity management is multi-sectoral. Genetic diversity within harvested species and closely related wild relatives has contributed enormously to the productivity of agriculture, aquaculture, fisheries and forestry. The short-term biological productivity of forestry, fisheries and agriculture may not be strictly dependent on biodiversity in the broadest sense; however, decreasing diversity in ecosystems that support these sectors will at some point – it is not clear where – have adverse impacts on their resilience, productivity and stability. At the same time, these sectors, as well as those not directly tied to biological resources, such as transportation, manufacturing, energy and minerals, and health and sanitation, play significant and direct roles in reducing diversity at the ecosystem, species, populations and genetic levels.

13.1.3 Methods and tools for biodiversity management

There are many methods and tools available for the management of biodiversity. Some have been developed to protect or restore particular species, genetic strains or habitats. Others are used to produce goods and services sustainably from biological resources. Some are intended to facilitate the equitable distribution of benefits from the conservation and sustainable use of biodiversity. These approaches can be categorized in the following way:

1. **In situ approaches** include methods and tools that protect species, genetic varieties and habitats in the wild. Which actions are used depends on the management objective. Most often, *in situ* approaches involve the establishment or management of protected areas such as strict nature reserve/wilderness areas, national parks, national monuments/natural landmarks, habitat/species management areas, protected landscapes and seascapes, and managed resource protected areas (see 13.4.2.1) (IUCN 1994). However, *in situ* approaches also include wildlife management and resource protection strategies outside protected areas. In agriculture and forestry, *in situ* methods are sometimes used to protect genetic diversity in crops and trees in the field or forest.
2. **Ex situ approaches** include methods that remove plant, animal and microbial species and genetic varieties from their environment. This is done for breeding, storage, cloning or rescue in cases where either (1) habitats can no longer sustain these elements because of site alteration or transformation, or (2) materials can be used to facilitate research, experimentation and development of new products, and public awareness. Such methods include botanic and zoological gardens, mycological collections, museums, seed banks, tissue culture collections, etc. Because the organisms are maintained in artificial environments, *ex situ* methods isolate species from evolutionary processes. This problem can be partially addressed by linking *ex situ* interventions to *in situ* programmes wherever possible.
3. **Restoration and rehabilitation approaches** include methods that draw upon *in situ* and *ex situ* tools to re-establish species, genetic varieties, communities, populations, habitats and ecological processes. Ecological restoration usually involves the reconstruction of natural or semi-natural ecosystems on degraded lands including the reintroduction of most native species, while ecological rehabilitation involves the repair of ecosystem processes, such as nutrient cycling or hydrologic regimes, but not necessarily the recreation of a natural ecosystem and its full complement of species.
4. **Major land-use approaches** include tools and strategies in forestry, fisheries, agriculture, wildlife management and tourism to incorporate protection, sustainable use and equity criteria and guidelines into management objectives and practices. Since these land uses dominate most landscapes and the nearshore coastal zone, these approaches are often where the greatest returns on investments in biodiversity management will be found.
5. **Policy and institutional approaches** include methods that limit the use of land resources through zoning

schemes; use incentives and tax policy to foster particular land-use practices; create and enforce land tenure arrangements that promote stewardship, and establish easements and other arrangements between public agencies and private interests that seek to establish landscape characteristics favourable to biodiversity.

It is impractical to pursue sustainable use or protection measures for every single species since there are so many, each with relatively specific requirements. Instead, measures usually emphasize maintaining habitat conditions that support many – perhaps tens of thousands – of species. But even at ecosystem levels of organization, their highly variable and dynamic nature can call for different approaches according to habitat type, ecosystem function and other variables (see Sections 5 and 6). For example, maintaining grassland ecosystems may require interventions of fire on a regular basis since many grassland species reproduce only after such disturbances. In contrast, moist forests, in which species have not adapted to frequent fire, may need to be protected from fire.

Programmes to manage biodiversity in any given area will normally employ a set of mechanisms and tools that, taken together, manage various problems, threats and human demands. For example, the public and private institutions of a country might simultaneously:

- establish parks and reserves to protect and regulate the use of ecologically valuable and sensitive habitats;
- form seed banks and microbial culture collections to maintain viable samples of germplasm;
- foster practices in forestry, fisheries, rangelands, agriculture and tourism that protect soil biota and the range of species and varieties of the region while maintaining productivity;
- initiate projects that combine the technical tools of botanical and zoological gardens and on-farm activities to help restore degraded areas;
- a range of land-use planning and zoning tools in urban and rural areas; and
- institute associated laws, policies and administrative procedures to facilitate these measures.

A piecemeal approach, characterized by a disjointed list of activities and lack of co-ordination among implementing institutions, will fail to protect or sustainably use many valuable elements of biodiversity.

An integrated biodiversity programme is one that features:

- a set of approaches, tools and mechanisms (e.g. protected areas, seed banks, rural zoning) designed to

address threats (e.g. habitat conversion), problems (e.g. unsustainable use practices) and opportunities (e.g. fostering new enterprises through biotechnology);

- a combination of interrelated measures to produce needed material and economic goods, and ecological, cultural and spiritual services, for the least cost and intervention; and
- a whole strategy that can be placed within the social, economic, political and institutional context with minimum disruption. Where major reforms and new initiatives are needed, the disruption associated with establishing new institutions (or changing farming practices) may require some time for accommodation by agency employees and local residents.

The degree to which biodiversity and biological resources are used sustainably and conserved, will depend in large part on how these various approaches have been integrated.

13.1.4 Approaches for managing biodiversity in a complex world

Biodiversity management programmes can improve the odds of success in dealing with complexity and uncertainty by employing the following three approaches: strategic planning, managing at bioregional or ecosystem scales, and using adaptive management techniques.

In all three approaches, broad participation is vital to success. People in the public and private sectors, and a wide variety of institutions (e.g. natural resource management agencies, universities, museums, zoos, botanical gardens, non-governmental organizations, communities and business) can contribute a great deal to the planning and implementation of biodiversity management programmes. For example, experience with the preparation of national biodiversity strategies and action plans demonstrates that this is true in developed and developing countries alike (Miller and Lanou 1995). Other research (e.g. Kiss 1990; Lynch 1992; Wells 1995) suggests that only through participatory planning can local interests be expected to share responsibility for implementation.

13.1.4.1 Strategic planning

A planning process should identify vital links between biodiversity, environmental and human health, and the natural resource base that sustains livelihoods and provides new options for social and economic development. A productive biodiversity planning process can identify those activities and investments that most effectively strengthen these linkages. These are strategic considerations. Not simply a new ‘add-on’ to traditional planning, this process seeks nothing less than the integration of strategic biodiversity considerations throughout national development plans.

Article 6 of the Convention on Biological Diversity calls upon countries to ‘Integrate, as far as possible and appropriate, the conservation and sustainable use of biological diversity into relevant sectoral or cross-sectoral plans, programmes and policies’. Clearly, responding to these provisions of the convention can serve as a comprehensive basis for planning and implementing an integrated programme for the protection and sustainable use of biodiversity.

National biodiversity strategies, action plans or programmes – as called for under Article 6 of the Convention on Biodiversity and in Agenda 21 – are intended to identify appropriate conservation and sustainable use measures and specify how they will be implemented. A growing number of countries (including Canada, Chile, Germany, Indonesia, Norway, the UK and Vietnam among others) have published or begun to develop national strategies and action plans. In most cases, these strategies and action plans represent the first planning tools that go beyond the piecemeal and incomplete efforts that have characterized conservation and sustainable use programmes in many countries prior to the stimulus of the convention.

While there is considerable variation in the approaches being followed by each country, the following distinctions between strategies and action plans are useful (Miller and Lanou 1995):

National Biodiversity Strategies are general policy instruments that identify strategic needs for the effective conservation of biodiversity. They draw upon descriptive and quantitative data and information to identify conservation goals and objectives, evaluate options to achieve goals, consider benefits and costs, and propose broad steps or policy actions that can be taken to improve conditions for biodiversity conservation.

Biodiversity Action Plans are frameworks used to identify more specific steps that can be taken by policy-makers, sectoral institutions and others to implement the national strategy. Action plans are practical documents specifying what protection and use measures will be taken; which institutions are responsible for which measures; what personnel, facilities; and finance will be employed; timetables; how NGOs and private organizations can be involved, and whether international co-operation is needed, and how it would be implemented.

A synthesis of the experience of 17 countries engaged in the preparation of national biodiversity strategies and action plans suggests that there are seven indicative steps to the biodiversity planning process. The UNEP-sponsored project outlines these steps, as shown in Box 13.1-2 (Miller and Lanou 1995).

These plans are **cyclical** in that they are constantly revolving around the seven steps outlined in Box 13.1-2. They are also **iterative**, leading to a continuous series of ever more detailed and specified versions of the plan over time, each version benefiting from new information and knowledge, further dialogue, expanding constituencies, and feedback from the implementation, monitoring and evaluation of past experience.

More significant than the product of planning – a written document or plan – is the **process** itself. Participants deeply involved in biodiversity planning often find that the greatest value in working in a strategic planning process is from the exercise itself. The first stages bring the stakeholders together, gather and evaluate information and

knowledge, define goals of common interest, and develop and adapt methods and tools to be used to achieve those goals. Other aspects include sharing responsibilities for actually implementing agreed plans and evaluating the results, having participating agencies, groups and individuals develop an understanding of biodiversity management goals and opportunities, and building a sense of ownership of the ensuing programmes.

As important as national biodiversity strategies, action plans and related programmes are in their own right, their impact will be greatest when they are part of broader strategies for long-term national development. Carew-Reid *et al.* (1994) provide examples of how biodiversity planning efforts can fit within a strategy for national sustainable

Box 13.1-2: Steps for strategic biodiversity planning.

1. **Getting organized.** Establish the institutional framework; designate leadership; create the participatory approach; form the interdisciplinary and inter-sectoral team; assign a budget.
2. **Assessment.** Gather and evaluate information on the status and trends of the nation's biodiversity and biological resources, laws, policies, organizations, programmes, budgets and human capacity. Create a preliminary statement of goals and objectives, identifying gaps, conduct a first review of options to close gaps, and make a rough estimate of costs and benefits and unmet needs associated with a national biodiversity programme.
3. **Developing a strategy.** Determine goals and operational objectives; analyse and select specific measures that will close the gaps identified in the assessment; further consult and modify until consensus is reached on acceptable targets and mechanisms; characterize stakeholders and what they can do; write a statement of the strategy, consisting of the actions and investments called for to meet the goals and objectives; at this stage consult closely with other conservation and development plans and sectors, including conducting a national dialogue with all interested stakeholders.
4. **Developing a plan of action.** Determine which organizations (public and private) will take charge of implementing specific activities included in the strategy, where, by what means, and with what resources (people, institutions, facilities and funds). Identify time phases for action.
5. **Implementation.** Launch activities and policies in practical terms. Partners take responsibility for particular elements of the plan and biodiversity planners become 'biodiversity implementors' in the key ministries, non-governmental organizations, communities, indigenous groups, business and industry involved in the planning process.
6. **Monitoring and evaluation.** Establish indicators of success, determining which organization(s) will monitor which factors and the methods that will be employed. Monitoring should track the status and trends of biodiversity (species, genes, and habitats and landscapes), implementation of policies and laws, implementation of specific strategic actions and investments, and the development of needed capacity (people, institutions, facilities and funding mechanisms).
7. **Reporting.** Determine what types of reports are needed, who is responsible for reporting, and agree on format, content and timing of the delivery of documents. Types of reports might include:
 - annual status reports to the national chief executive, parliament, and the people;
 - country study;
 - national strategy;
 - action plan;
 - five-year status report on biodiversity and biological resources; and
 - periodic reports to the Convention, the UN Sustainable Development Commission, and other international forums.

development that seeks to define and implement actions to improve and maintain the well-being of people and ecosystems. Other important works available to assist countries with strategic biodiversity planning include publications on: environmental impact assessments (World Bank 1991), country study guidelines (UNEP 1993), and the economics of biodiversity (McNeely 1988; Pearce 1993).

13.1.4.2 *Bioregional and ecosystem management programmes*

The effective protection, understanding and sustainable use of biodiversity and biological resources require that objectives are identified and actions are implemented at geographic and time scales consistent with the biological, social and economic processes affecting the achievement of those objectives. This approach to resource management is often referred to as bioregional management, ecosystem management, or landscape management. Only in this way can management provide for the flexibility and variety of options needed to accommodate human aspirations, while ensuring the protection of critical genetic, species and habitat diversity, and the maintenance of ecosystem services. For example, the conservation of migratory species requires that objectives be set and priorities established across broad geographic areas. Similarly, efforts to integrate conservation and development near a protected area require objectives that are set at a scale that can address such issues as marketing opportunities, the potential for migration of people to the region, and the resource needs of surrounding communities. Typically, conservation programmes are too small in scale to meet the habitat requirements of some species. More generally, objectives for conservation and resource management are too often identified at scales too small to make either economic or biological sense. For example, the cumulative effects of many small resource management decisions – each with minimal impact in its own right – can lead to significant landscape changes that are unappreciated at local levels.

Biodiversity conservation objectives can be addressed more successfully by expanding the area to be managed beyond protected areas, to the bioregion or landscape scale. This calls for co-operative arrangements with private landowners, local governments, communities and corporations, present in the region. By working with surrounding landowners and residents, biodiversity managers can better meet biodiversity management objectives.

Such ‘bioregional’ or ‘ecosystem management’ approaches are being put to the test in various parts of the world. In most cases, these approaches build upon existing protected areas or highly valued biodiversity sites, and establish institutional arrangements that encourage public

and private sector co-operation across whole landscapes. Ideally, a bioregional management programme will feature:

1. an **ecological** component consisting of areas protected for their biodiversity value and interconnected where possible by corridors of natural or semi-natural habitats;
2. an **economic** component that supports the sustainable management and use of natural resources in the matrix of farms, grazing lands, managed forests, industry, villages and infrastructure; and
3. a **social/cultural** component that facilitates the participation of local people in resource planning and decision-making and provides opportunities for people to meet a variety of social and cultural needs.

At the heart of such a programme lies a set of institutional mechanisms that enables the diverse public, civic and private interests to negotiate and implement their plans. These are complemented by support mechanisms from universities, and public, community and private agencies and other organizations that assist decision-making with information, knowledge and experience. Local residents, industry, and public agency leaders are encouraged to join in formulating a common vision for the region. Such a vision would identify needed actions and investments. The group would take responsibility for implementation, evaluation and monitoring of results.

Considerable experience in bioregional management has already been gained (e.g. Hudson 1991; Brown and Wyckoff-Baird 1992; Golley 1993; Aberley 1994; GAO 1994). Examples include the tri-country Waddensee programme along coastal Denmark, Germany and the Netherlands (Wadden Sea Assessment Group and Trilateral Working Group 1991); Greater Serengeti Ecosystem in Kenya and Tanzania (Tanzania Ministry of Tourism, Natural Resources and Environment 1991); La Amistad Biosphere Reserve in Costa Rica and Panama (Gobierno de Costa Rica 1990); Great Barrier Reef Marine Park Authority, Australia (Murdoch 1992); and Greater Yellowstone Ecosystem, United States (Rawlins 1994). Costa Rica has embarked on an ambitious strategy to develop bioregional management programmes centred on eight of its protected areas (see Figure 13.1-1). Within each of these regions, which extend beyond the formal protected areas, a variety of land uses and biodiversity management activities are planned (Gobierno de Costa Rica 1990).

One of the key institutional challenges in bioregional management is to establish an appropriate balance between national and local control over resource management (Miller 1995). Achieving an effective balance between the authority and responsibilities of various levels of government, from the national to the local, will often

Figure 13.1-1: Bioregional management involving eight conservation areas in Costa Rica. (From WRI/IUCN/UNEP 1992.)

require steps to return or establish local ownership and tenure of resources, or to centralize certain rights and responsibilities. Centralization of management requires mechanisms for law enforcement and control; decentralization necessitates participation and joint management. Centralization can be important in protecting national interests or minority interest in the sustainable management and use of natural resources that might otherwise succumb to pressures for rapid depletion. Decentralization and the use of co-management strategies, on the other hand, enables local communities, private companies and non-governmental organizations (NGOs) to join governments in defining and implementing policies to conserve and use biological resources sustainably.

The North York Moors National Park in the United Kingdom serves as an example of a co-management arrangement (Statham 1994). There, farmers living within and around the park have the opportunity to collaborate with the parks agency to restore the hedgerow habitat that is vital to biodiversity management in the region. The park offers farmers a co-operative contract whereby farmers are paid to restore and maintain hedgerows of vegetation along designated boundaries of their fields and pasture lands.

While bioregional management offers opportunities to

address biodiversity protection, use and equity objectives in ways that can respond to the dynamic and unpredictable features of ecosystems and human society, challenges abound. Obstacles to the implementation of bioregional programmes include:

- a lack of mandates for public agencies to provide the leadership needed to organize such programmes;
- a lack of capacity to manage the various technical and administrative tasks involved in shifting to larger territories;
- the absence of incentives for stakeholders to become involved in defining and negotiating equitable arrangements;
- the inability of government programmes to adjust their investment and programme cycles to fit the social traditions, mechanisms and needs of residents;
- a lack of political will to establish or support the authority to integrate and co-ordinate existing institutions; and
- a failure to establish long-term funding mechanisms that compensate residents who trade off benefits or carry increased costs as a result of their co-operation (Miller 1995).

Nevertheless, a rapidly growing body of scientific literature and practical experience suggests that the relationship between scale – both geographic and temporal scales – and biodiversity management deserves much greater attention.

13.1.4.3 Adaptive management

Adaptive management practices can reduce uncertainty and improve resource management through time. The effectiveness of management practices that influence biodiversity is constrained by incomplete knowledge of biodiversity and by the dynamic nature of living systems. Establishing goals for the conservation of biodiversity and the sustainable use of its components is hindered by limited knowledge of such basic issues as the identity of most species, the role of specific components of biodiversity in various ecological processes, the vulnerability of ecosystem services to the loss of diversity, and the economic implications of changes in diversity. Goal setting and the attainment of goals is also hindered because biological systems are dynamic – populations of species evolve in response to selection pressures, the composition of ecological communities shifts with changes in climate, and species migrate into or are lost from particular communities. Consequently, even if a vision of a desirable future could be developed, the path to its fulfilment could not be mapped with precision. So too, human societies and their values change. For example, what society demands and expects from its forest resources today is quite distinct from 20 years ago (Gordon 1993). Biodiversity management is always undertaken in the face of substantial uncertainty.

Adaptive management is a technique for managing biological systems while also reducing uncertainty about the functioning of the systems and responding to the changing social, biological and physical environment. Gunderson *et al.* (1994) advocate ‘adaptive management’ measures that accept change as a basic reality and seek to plan with, around and through change.

The principal elements of adaptive management are:

1. that management interventions are made in an experimental manner so that the outcome of the intervention can be used to reduce uncertainty about the system;
2. that sufficient monitoring prior to and during the intervention enables detection of the results of the management intervention and thereby allows managers to learn from past experience; and
3. based on the feedback to managers, communities and other constituencies, management interventions are then refined.

Adaptive management techniques are also vital for biodiversity management since there is limited experience with many tools, methods and approaches. Because of this, assessments of their effectiveness are often incomplete or non-existent. The adaptive management approach, therefore, is particularly useful when decisions need to be made in the absence of data, where uncertainty is great, and where social and biological change are inevitable.

13.1.5 Conclusion

This chapter has shown that a comprehensive and integrated framework is vital to the complex task of managing biodiversity for conservation, sustainable use and benefit-sharing objectives. However, it is not enough simply to integrate an array of biodiversity management approaches into the planning process. Most actions to conserve, sustainably use, and share the benefits of biological resources are implemented in specific places where biodiversity and human activities are linked at many scales. Biodiversity management is not simply a question of establishing parks or reserves as islands of protection in a sea of unregulated agriculture, forestry, fisheries and urban development, or of setting up agricultural seed banks without links to on-farm conservation plots. Rather, biodiversity management includes the steps required to incorporate conservation and sustainable use practices within all components of the overall landscape, supported by policies, agreements and institutional arrangements that foster co-operation. The following chapters assess the tools, methods, approaches, and capacities required to manage biodiversity successfully within an integrated framework.

13.2 Defining priorities for conservation and sustainable use

13.2.1 Introduction

The development of strategic plans, including national strategies and action plans (see 13.1.4.1), will require choices to be made about resource allocation in order to maximize the long-term benefits that biodiversity can provide. Investments in the conservation and sustainable use of biodiversity, however, have rarely been made in a systematic, analytical and transparent manner. This chapter presents an overview of techniques for setting geographic priorities to conserve and sustainably use biodiversity.

All approaches to priority-setting are based on the assumption that the need for resources to conserve biodiversity will far outstrip the resources that are available. This assumption is expected to remain valid throughout the 1990s and beyond (Abramovitz 1994). Deciding which species and habitats have precedence in the allocation of limited financial, human and institutional resources is likely to remain a difficult but inevitable task for the foreseeable future.

Given the complexity of biodiversity and the range of values, perspectives and goals that influence how biodiversity is viewed, it is not surprising that there is no generally accepted universal scheme for establishing biodiversity priorities (Forey *et al.* 1994; Johnson 1995). Any set of conservation priorities reflects human values. In order to distinguish between the almost infinite variety of genes, species and ecosystems, priority-setters assign values to elements of biodiversity. These values may represent economic, scientific or social and cultural benefits from biodiversity that people and institutions consider most important for long-term conservation.

Most structured approaches to identifying biodiversity priorities have been focused on *where* actions are needed to protect biodiversity. Only a few efforts have been made to evaluate systematically *what* should be done in these areas. Many approaches were specifically designed to establish or revise protected area systems to best capture elements of biodiversity; many of the rest implicitly assume that some form of protection activity should take place in identified areas. It should, however, be noted that virtually all forms of geographically based priority-setting approaches can be used simply to identify where valuable biodiversity for a particular protection or sustainable use objective is located.

The geographic priority-setting approaches described here can, in theory, be used to identify where, geographically, to

focus changes in forest management policies and practices (see 13.3.3), how to target the collection of plant species for *ex situ* preservation and breeding, or where bioregional management efforts are most needed in order to integrate a wide range of conservation and sustainable use activities. Unfortunately, it is more difficult to assess what needs to be done as opposed to where something should be done. At the local and community level, rapid rural appraisal and other techniques are being used to identify the most effective or urgently needed actions (Shengji and Sajise 1995). At the national and international level, the requirements of the Convention on Biological Diversity have been used to analyse priorities in terms of what needs to be done (e.g. Rojas and Vallejo 1994) and a variety of countries have used various processes to do this while developing national biodiversity strategies and other national plans (see Miller and Lanou 1995). Many methods of setting geographic priorities for a wide range of conservation and sustainable use objectives have emerged over the last decade. Some are based on *genetic* analysis (i.e. use of genetic information to select populations or areas), some on *species* analysis (i.e. the distribution of particular species, aggregations of species, taxonomic groups and rates of species endemism), and some on *ecosystem* analysis (i.e. the distribution of distinct natural communities, ecosystems and ecosystem processes). These three categories of methods rely mainly on biological information, but may use any of the biological or social and institutional criteria (see Box 13.2-1). A fourth category comprises *integrative* methods that include significant consideration of economic, social and cultural factors in addition to biological factors.

No single priority-setting method fits all conservation objectives. For example, if the objective is to conserve a representative array of a country's natural ecosystems, a priority-setting approach that relies on species richness may neglect to represent important ecosystems that are relatively species-poor.

13.2.2 Genetically based methods for establishing priorities

Genetic variation underlies the more visible diversity of life that we see expressed in individuals and populations of a particular species, the different species themselves, and the higher taxonomic orders to which species belong. With the rise of biotechnology and the perception that genes are the grist for the next (or current) technological revolution, genetic diversity has become the focus of increased research – and also increased controversies over who ‘owns’ genetic resources and who benefits from their conservation.

Traditionally, efforts to characterize and conserve genetic diversity have been dominated by an emphasis on domesticated plants, particularly a few dozen agriculturally

Box 13.2-1: Criteria used for biodiversity priority-setting.

Any deliberate priority-setting effort uses various criteria to reduce the number of elements of biodiversity considered for priority status. The complexity of biodiversity and the number of ways of valuing it make a host of criteria theoretically possible, but only a handful of them are commonly used. Among the biological criteria are *richness* (the number of species – or ecosystems – in a given area), *rarity*, *threat* (degree of harm or danger), *distinctiveness* (how much a species differs from its nearest relative), *representativeness* (how closely an area represents a defined ecosystem), and *function* (the degree to which a species or ecosystem affects the ability of other species or ecosystems to persist).

Some priority-setting approaches use social, policy and institutional criteria as well. *Utility*, the most common non-biological criterion, points to biodiversity elements of known or potential use to humankind. Utility may be narrowly defined as economic value, but in a broader sense it can signify scientific, social, cultural or religious significance as well. *Feasibility*, often paramount in deciding how to allocate conservation resources, may be defined in political, economic, logistical or institutional terms. Considering feasibility along with biological criteria helps identify areas where actions are most likely to succeed. These criteria are newer entries to the field than biological criteria, but their use will increase alongside growing recognition that social, policy and institutional factors are crucial to conserving biodiversity.

Source: Johnson (1995).

important species. A growing number of agricultural research institutions have sought ways to limit genetic vulnerability – a uniformity of genotypes that leaves crops vulnerable to new environmental stresses, pests and disease – by preserving the range of genetic diversity found in crop species and their wild relatives. During the past 20 years, endangered species recovery programmes have stimulated considerable research on the genetic variability of remaining individuals and populations to find ways of ensuring that populations do not succumb to a combination of inbreeding and a narrowed genetic base. Others are interested in conserving genetic diversity within populations because of their potential for future utility (see Ledig 1988), or because a decline in diversity represents interference in the evolutionary process and the loss of evolutionary potential (see, for example, Mlot 1989; Hamilton 1993).

Genetic resources can be conserved *in situ* in reserves or special management areas, or in *ex situ* facilities such as seed banks, zoos, botanical gardens, aquaria, etc. Even as collectors take plant cuttings or shake seeds of a specimen into an envelope for *ex situ* preservation, or as conservation biologists protect the habitat of an animal population for *in situ* conservation, they are deciding which genes of a species are most likely to persist, especially if the species is rare or highly endangered. This is where genetically based approaches to identifying conservation priorities are needed. They are used to support three general objectives:

- to ensure that individuals representative of genetic variability within a species are included in conservation programmes;
- to help determine which population(s) contain the greatest genetic variation; and
- to conserve populations across their geographic range and the ecotypes in which they are found to ensure that co-adapted gene complexes (i.e. groups of alleles on one or more genes that adapt to the same selective pressures experienced in a particular environment), are conserved, and not just a representative sample of alleles.

Tools used for identifying genetically based conservation priorities range from simple surrogate measures of underlying genetic variation (e.g. variation in plant or animal morphology) to highly sophisticated molecular genetic techniques. In most cases, analysis of enzyme variants (allozymes) is used to gauge the overall genetic variability within a species, a population or a number of populations. Sampling strategies can be complex, and considerable debate about the advantages and disadvantages of different sampling techniques is seen in the literature. These issues are beyond the scope of this publication, and are discussed in detail elsewhere (see Schonewald-Cox *et al.* 1983; Hartl and Clark 1990; Falk and Holsinger 1991).

In most areas of the world, where information is scarce, species are numerous, and threats to diversity at all levels are acute, genetically based approaches should probably be viewed as a secondary strategy for identifying conservation priorities. Genetically based approaches should be used to 'fine-tune' priorities once the 'coarse filter' provided by ecosystem-based approaches (complemented by species-based approaches) has been applied. Woodruff (1992) suggests that ecological management is the cheapest and most effective way of conserving genetic diversity:

Genetic factors do not figure among the four major causes of extinction: overkill, habitat destruction and fragmentation, impact of introduced species, and secondary or cascade effects (Diamond 1989). Thus,

although genetic factors are major determinants of a population's long-term viability, conservationists can do more for a threatened population in the short-term by managing its ecology.

Nevertheless, genetically based approaches to identifying conservation priorities are pivotal in some circumstances. These include setting priorities for small, isolated populations; for genetically vulnerable species of high economic or other value; and for identification of individuals or populations for which there is no conservation alternative to *ex situ* preservation in the short term.

13.2.3 Species-based methods for establishing priorities

The species is the unit or element of the biodiversity spectrum – from genes to large-scale ecosystems – most commonly used by scientists and the public to represent biological variation (see also Sections 1 and 2). On the one hand, species are the most recognizable expression of taxonomic diversity. At the same time, species are the building blocks of ecosystems (McNeely *et al.* 1990). Not surprisingly, more biodiversity conservation efforts focus on species (populations of which are the immediate target of most conservation efforts) than on genes, communities or ecosystems. Likewise, most approaches to setting biodiversity-conservation priorities have relied heavily on the species as the basic unit for analysis.

The key feature of species-based approaches is their emphasis on the analysis of population sizes and geographic distributions of individual species to identify priorities. The species-based approach to setting priorities generally does not include analysis of biodiversity at higher levels of organization such as communities, ecosystems, ecosystem processes or biogeographic features. A species-based approach may express priorities in terms of specific sites or habitats, but the habitat is not necessarily chosen on the basis of its rarity or uniqueness. For example, the Kirtlands warbler (*Dendroica kirtlandii*) is one of the world's most endangered songbirds, and its nesting sites are a conservation priority. These nesting sites are found in jack pine (*Pinus banksiana*) forests in lower Michigan, a tree species that is widespread in upper Michigan, Minnesota and Canada. A species-based approach emphasizes the value of individual species. In this way it is different from ecosystem-based approaches, which emphasize the role of species interactions and ecological processes as factors important to the conservation and use of biodiversity and the role that ecosystem priorities can play in capturing a significant proportion of diversity at genetic and species levels. Species-based approaches usually emphasize conservation of individual species that are rare or endangered, or habitats characterized by a high degree of species richness and/or endemism. The first type of species-based approach often generates considerable

response from the general public and political authorities. In practice, individual species that are ‘charismatic’, ‘flagship’, or otherwise culturally prominent, and those that are endemic to a country or smaller area, tend to receive more attention than other species. Programmes to save the tiger, the giant panda, or the California condor are well-publicized examples of such single-species conservation priorities.

The second type of species-based approach is aimed at protecting habitats that are important to certain taxonomic groups. The best-documented world-wide examples to date are 221 endemic bird areas, which have unusual concentrations of restricted-range bird species (Bibby *et al.* 1992), and 234 centres of plant diversity, which have exceptional degrees of plant species richness and endemism (WWF and IUCN 1994–5).

Perhaps the most institutionalized system for ranking species-based conservation priorities is the one developed by The Nature Conservancy for use by its Natural Heritage programmes in all 50 US states and in Conservation Data Centres in 13 Latin American countries and several Canadian provinces (see Box 13.2-2), but there are numerous others.

A growing number of the Specialist Groups under the IUCN Species Survival Commission have developed ranking systems to evaluate the conservation needs for species, populations and habitats for distinct groupings of wild animal and plant species (Eudey 1987; Schreiber *et al.* 1989; Cumming *et al.* 1990; Stuart *et al.* 1990). Hawkes (1988) has developed a system for ranking economically useful plants.

Species-based approaches have a number of advantages. They allow one to focus selectively on the elements of biodiversity that are most endangered, or those that are most valued from a particular perspective. For example, the conservation of agricultural diversity relies on species-based approaches since ecosystem-based approaches do not pinpoint agriculturally important species, varieties or populations. Moreover, a focus on certain species may result in many others also being conserved. Examples include ‘keystone species’, which have a critical role in whole ecosystems, and ‘charismatic megavertebrates’, which are large and spectacular, and attract public attention. It is often easier to mobilize public opinion in support of such species than for more subtle ecosystem conservation priorities.

One problem with using species-based approaches to setting priorities is that the knowledge of variation at the species level and below is often poor. Therefore, it is difficult to conserve the representative genetic variation within a species. Another problem with species-based approaches is that action may occur only after it has been determined that a species is endangered – when it is too late or too costly to save a broad sample of the genetic

Box 13.2-2: Natural Heritage System priority ranking.

The Natural Heritage System uses a priority-ranking system to identify elements of natural diversity – plant and animal species, subspecies, and natural communities or habitats – that are most important for conservation. In practice, the ranking scheme is used primarily with species of vertebrates and plants (Master 1991). The species ranks are based on information about each species for a series of criteria including the known or estimated number, quality and condition of element occurrences (i.e. locations of sub-populations of the species); the estimated number of individuals; narrowness of range and habitat; trends in population and habitat; threats to the element; the element’s fragility; and other factors (Master 1991). Using a 1–5 scale, this information is then used to assign a rank to the species at three separate scales – global, national, and state or province.

When the global, national and sub-national ranks are combined, the system allows for a rapid assessment of the species’ known or probable threat of extinction or extirpation in a particular jurisdiction. For example, a species ranked G5/N2/S1 is extremely vulnerable to extirpation at the state or provincial level, vulnerable (but not critically) at the national level, and widespread and abundant globally with no threat of extinction.

In practice, The Nature Conservancy and its partners do not use the ranking system alone to set priorities. With each species or element record, information is included on recommendations for protection, inventory, research and management. These recommendations are frequently based on a number of site-specific facts and qualitative assessments of the species conservation needs and are crucial determinants of follow-up actions. In most cases, conservation actions are not directed at an individual species but instead focus on sites that have more than one priority species. To choose among such sites, The Nature Conservancy uses a 1–5 scale to assess ‘site biodiversity significance ranks’ and ‘site protection urgency ranks’. The former focus on the overall condition, viability and representativeness of the sub-population while the latter assess the relative threat of destruction to the site.

variability of the species’ populations. If entire ecosystems are threatened, not merely isolated species, the ecosystem approach is often preferred. Species-based approaches, however, need not be applied only when the species has become critically endangered.

Most species-based approaches to conservation assume that all species are taxonomically equivalent. For example, when species richness is used to identify priorities, each species is given equal weight as decisions are made about where to focus conservation efforts. This assumption is troubling for many biologists who believe that some species are more important than others. In particular, conserving species that are the only representatives of a genus, family or higher taxonomic group will do more to conserve biodiversity than saving species with many close relatives at the genus or family level (see also Section 7).

In recent years, a number of approaches to setting priorities have used systematics (the study of genetic and evolutionary relationships between species) as a major tool for determining conservation priorities. The key difference from other species-based approaches is that elements of biodiversity (i.e. species) are assigned value based on their taxonomic distinctiveness. In other words, given two highly threatened taxa, one a species not closely related to other living species (e.g. the panda), and one species closely related to other more common species (e.g. the Kirtlands warbler), it is the more taxonomically distinct panda that would be accorded higher priority.

Using cladistic analysis – classifying organisms on the basis of evolutionary relationships – and quantitative weighting techniques, a growing number of approaches have been developed to identify priorities, at least partly, on the basis of taxonomic distinctiveness (see Daugherty *et al.* 1990; May 1990; Vane-Wright *et al.* 1991, 1994; Faith 1994; Forey *et al.* 1994).

WORLDMAP is an example of a priority-setting tool based on the evaluation of taxonomic relationships (Williams and Humphrey 1994). It uses a specialized geographic information system (GIS) to identify iteratively the minimum number of areas to represent all distinct taxa (sometimes referred to as ‘attributes’ by systematists) within a region. Similar programmes, such as DIVERSITY (Faith and Walker 1994), CODA (Pressey *et al.* 1994) and ERMS (Margules *et al.* 1994), are being tested for the design of protected area networks and land-use suitability classification, particularly in Australia.

The use of systematics in priority-setting efforts is appealing because it provides a firm biological and evolutionary basis for conservation. Such approaches have the potential to maximize the conservation of evolutionary pathways that more traditional species-based approaches do not. The combination of quantitative measures of taxonomic distinctness with more familiar ecological considerations of abundance and geographic distribution is important for future conservation efforts (May 1990).

There are, however, serious limitations to using quantitative measures of species relationships to identify priorities (Johnson 1995). First, such approaches are even more limited by a lack of information than species-based

approaches – the cladistic relationships of the vast majority of organisms are unknown. Second, cladistic approaches are concerned mainly with conserving a representative genetic legacy of evolutionary history. While this is an important conservation objective, biodiversity has many conservation and use values that are independent of evolutionary history and taxonomic distinctiveness. Advances in systematics and the growing interest of systematists in conservation, however, suggest that the use of systematic tools to determine conservation priorities, in combination with other types of species- and ecosystem-based analysis, will expand in coming years.

Genetic- and species-based approaches to setting comprehensive conservation priorities are severely constrained by inadequate information for most areas of the world and for most species. Not only are there many more species than we thought there were ten years ago (see Section 3), but we have not been keeping up with the conservation needs of the few thousand known to be endangered. The rescue of those species has proved to be difficult, often ineffective, and extraordinarily expensive (Reid 1992). For these and other reasons, some approaches to setting conservation priorities are based on ecosystem or biogeographic classifications.

13.2.4 Ecosystem-based methods for establishing priorities

Ecosystem approaches to setting biodiversity-conservation priorities generally seek to protect most species within conservation areas that are representative of a region’s natural habitats. Ecosystem approaches for identifying conservation priorities use multiple criteria such as species richness, endemism, abundance, uniqueness and representativeness, as well as considerations of the physical environment, ecological processes and disturbance regimes that help to define ecosystems.

The basic objective of most ecosystem-based approaches is to conserve the range of ecological conditions found within the geographic scale of interest. Ecosystem-based approaches are sometimes favoured because they can be used as a surrogate for detailed species knowledge. But ecosystem-based approaches also have value since they can protect habitats that might never be considered by species-based approaches. For example, ecological approaches may identify sites such as migratory resting and feeding habitats, or important areas for the exchange of energy and nutrients such as mangrove forests, which species-based approaches overlook. Ecosystem-based approaches therefore can include areas with ecological functions vital to biodiversity – areas not readily captured in priority analyses based on a species approach.

Ecosystem-based priority-setting has advanced considerably in recent years. For example, Dinerstein *et al.* (1995) have developed methods for assessing the

conservation potential of ecoregions in the Latin American and Caribbean area. The intention of this work is to build up a layered model of each ecoregion incorporating landscape features, patterns of species richness and endemism, critical habitats and protected areas, management activities, human demography, and other social, economic and political factors that collectively influence conservation priorities for the ecoregion. This approach builds upon existing analyses while also incorporating much additional information. A different approach, which relies on the use of expert opinion, has been developed by Conservation International (Olivieri *et al.* 1995) and collaborating national and local organizations to rapidly assess priorities within a major biome or biogeographic region (for example, the Atlantic coastal forest in Brazil). Teams of experts review existing data and integrate their own experience and knowledge to develop priorities for major taxonomic groups which are then synthesized into a set of priorities for action.

Ecosystem-based approaches to setting conservation priorities have a number of strengths. For example, if representative ecosystems are conserved in large areas, the vast majority of species and much of their genetic diversity will be protected. In addition, ecological processes (e.g. nutrient cycling, hydrological regulation, micro- and meso-climatic regulation, and the maintenance of disturbance regimes upon which many species depend) are essential to the survival of many species. Only ecosystem-based approaches are likely to ensure the protection of these vital links to biodiversity. Finally, ecosystem-based approaches help conservation to protect biodiversity across a full range of habitats and across a broad geographic spectrum that species-based approaches to conservation may overlook. If little is known about species distributions and endangerment, ecosystem-based approaches are the only realistic option for analysis.

Several problems are encountered in efforts to set priorities on an ecosystem basis. For example, what constitutes a 'natural' ecosystem? Many ecosystem-based approaches attach priority to natural habitats (e.g. MacKinnon and MacKinnon 1986a). In reality, however, all ecosystems have been influenced to varying degrees by human activity, ranging from the impact of global pollution to that of historical hunting, logging, farming or grazing. In some areas, such as Europe, the Mediterranean and Japan, virtually all ecosystems show signs of heavy modification by millennia of human use.

Nevertheless, it remains useful for many purposes to distinguish between 'natural' and 'artificial' habitats. The former are those dominated by indigenous species living in approximately the same proportions as would be expected in the absence of human interference, or are in the process of returning to those proportions following human disturbance, and which meanwhile comprise a viable

reservoir of indigenous species and gene pools (Caldecott 1995). Artificial habitats, by contrast, are those dominated by introduced species, or by built environments, or by indigenous species occurring in relative abundance that have been grossly altered by people (e.g. forest plantations).

Ecosystem-based priority-setting is constrained by the fact that ecosystems vary greatly and are poorly understood. Ecosystems are difficult to define since their size, composition, complexity and distribution change with scale in both time and space. Not surprisingly, ecologists differ in their descriptions and definitions of ecosystems: despite many attempts to classify them, there is still no internationally recognized standard. Most countries are still without a consensus classification scheme, although there are efforts in some, such as Australia, to develop 'biogeographic regionalizations' based on attributes of climate, geology, landform, vegetation, flora, fauna and land use (Margules *et al.* 1994).

Finally, ecosystem-based approaches to identifying priorities usually fail to include all rare or potentially endangered species. Localized species will sometimes be left out of priorities determined by ecosystem analysis, especially in the tropics where most species ranges are typically small. There will always be some need for individual species-protection programmes, even if comprehensive ecosystem protection or management programmes are implemented.

13.2.5 Integrative approaches for establishing priorities

Since Aristotle, science has often had a tendency to break down complex phenomena into component parts and treat them as if they have little relationship to each other. Biodiversity thus becomes genes, populations, species, communities and ecosystems, each with its separate constituent biological disciplines. The natural world is often viewed as standing quite apart from the human world – uncorrupted in the view of some, unharnessed in the view of others. Conservation priorities have frequently reflected these views: endangered species are to be protected in pristine natural habitats, protected areas sanitized of human influence.

However, during the past decade, reductionist ways of viewing nature and its biological composition have been challenged. Many ecologists, for example, believe biodiversity can be understood only by looking at all of the hierarchical levels and their interactions. At the same time, advances in ecology, palaeobiology and conservation biology are calling into question the very meaning of a 'natural' ecosystem. This has prompted some to go so far as to state that the overarching goal of ecological management should be to maximize human capacity to adapt to changing ecological conditions (e.g. Reid 1994), not some romantic notion of maintaining natural 'biological integrity'.

The more holistic views of biology, together with the realization that humans are almost everywhere an integral part of ecosystems, have begun to influence the way in which biodiversity–conservation priorities are set. These views emphasize the role that non-biological factors must play in setting conservation priorities, as well as the need to use diversified strategies that adapt to the myriad cultures and value systems around the world.

To accommodate the dynamic nature of ecosystems, integrative approaches to identifying biodiversity priorities emphasize looking across the entire landscape – protected and unprotected, natural and heavily modified. Such approaches seek to enhance the contribution biodiversity makes to human welfare, in addition to protecting certain areas from human activities. They emphasize the use of multiple biological and non-biological criteria. The objectives of such approaches are not only the preservation of biodiversity for its own sake, but maximizing life's capacity to adapt to changing conditions (e.g. climate change, sea-level change, altered species compositions, etc.). Often, it may be social, not biological, issues (the desire to have an environment that supports human welfare) that are the unifying force behind integrative approaches to identifying biodiversity conservation priorities. In practical terms, this means setting priorities in the human-dominated landscapes that are found over two-thirds of the Earth's land surface, and includes consideration of biodiversity conservation needs in urban and suburban environments (see McNeely *et al.* 1990).

Very few methods have been developed to identify conservation priorities outside of strictly 'natural' landscapes. Those that do exist are not so much methodologies for setting conservation priorities as criteria for assessing the social value of biodiversity in the landscape.

Perhaps the greatest limitation to the integrative approaches is that they may de-emphasize biodiversity values relative to other social, economic and political values. The consideration of non-biological factors as co-variables with biological factors can make it difficult to say whether a chosen priority is important mainly because of its biological values or because of the contribution of other variables. And, even where careful attention is paid to protecting the biological resources, it can be unclear which social, economic or political criteria are most important to conservation.

The main advantage of integrative approaches is that they link biodiversity to other natural resources and the values humans attach to them. This means that selected priorities will often have non-biological values that could strengthen political support for conservation actions. For example, a priority area that has significant watershed value or tourism potential (in addition to biodiversity value) may be more socially and politically viable than an

area selected solely for its biodiversity values. Integrative approaches, therefore, may minimize the narrowing of conservation priorities that often takes place when strictly biologically-based priorities are considered by policy-makers who are concerned about the economic, social or political implications of their decisions.

13.2.6 Experience in setting geographically-based priorities

The most visible efforts to establish conservation priorities in recent years have centred on identifying those parts of the world with the greatest biodiversity. These efforts are driven by several considerations.

1. Biodiversity is unevenly distributed around the world, with some nations having greater diversity than others, just as within a nation some ecosystems have more species than others.
2. Biological resources found in one area can have values of international or global significance, especially in terms of genetic resources for agriculture and pharmaceuticals.
3. Most of the world's species are found in the tropics where countries with limited capacity (e.g. personnel, institutions, facilities and funding) face enormous pressures on their biological resources.
4. Conserving biodiversity will require international investments to share the cost of maintaining biological resources whose benefits often flow beyond national borders.

Priority-setting schemes for identifying areas or sites of high conservation value based on a global or wide regional analysis have been developed by a number of authors. Some of these approaches include the 'hotspots' approach (Myers 1988, 1990), the 'megadiversity' countries approach (Mittermeier and Werner 1990), the conservation threat/potential approach (Dinerstein and Wikramanayake 1993), and an integrated priority-setting framework developed by a consortium of international conservation groups organized by the Biodiversity Support Program (BSP *et al.* 1995).

National and local biodiversity–conservation priority-setting has not received the level of attention that international priority setting has received. Relatively few countries have clearly defined conservation priorities, and even fewer have consensus priorities that are actively used to guide conservation activities or direct government and donor resources.

There are, however, a growing number of cases where priority-setting efforts have been applied specifically to influence the allocation of biodiversity-management resources at national or regional levels. These include reviews of protected area systems in the Afro-Tropical,

Indo-Malayan and Oceanian realms (MacKinnon and MacKinnon 1986a, b; Dahl 1986) which continue to be reviewed and updated (e.g. Braatz *et al.* 1992; SPREP 1992; MacKinnon 1994). Numerous national initiatives have also been undertaken including efforts in Brazil (IBAMA *et al.* 1991), Papua New Guinea (Swartzendruber 1993), Bulgaria (BSP 1994), the United States (Scott *et al.* 1993), Russia (Krever *et al.* 1994), Australia (Margules *et al.* 1994; Pressey *et al.* 1994), New Zealand (Atkinson 1994) and India (Daniels *et al.* 1991).

This work can be used to focus attention on sites that are consistently identified as being of special importance for biodiversity. Thus, there are already lists from some countries of sites that must be protected or managed sustainably if key components of their national biodiversity resources are to be retained. An example is provided by the 80–90 sites in Indonesia that were identified as vital by the country's National Conservation Plan (FAO 1982), and later studies by the Ministry of Transmigration (RePPPProt 1990), the Ministry of Forests (MoF/FAO 1991), the Ministry for Environment (Government of Indonesia 1992) and the National Development Planning Agency (Government of Indonesia 1993). Locations where national and international priorities coincide in this way are logical candidates for investment in biodiversity management and protection.

Nearly all efforts to set priorities have focused on terrestrial areas, and marine ecosystems have been largely neglected. This probably reflects the terrestrial bias of biodiversity management in general. Priority-setting for coastal and marine biodiversity has also been hampered by a lack of biogeographic classification for marine ecosystems. Recent efforts have begun to address this problem at a global level.

The IUCN's Commission on National Parks and Protected Areas (CNPPA), the Great Barrier Reef Marine Park Authority (GBRMPA), and the World Bank launched an ambitious project in 1991 to identify priority areas for the conservation of marine biodiversity (Kelleher *et al.* 1995). The ultimate goal of the project – consistent with resolutions passed at major conservation forums such as the 1988 IUCN General Assembly – is to establish a global network of protected areas that includes all of the world's distinct marine ecosystems.

The CNPPA developed its own system based on biogeographical considerations (i.e. physical, vegetational and faunal characteristics) and political boundaries. The world's marine areas were divided into 18 regions, such as the wider Caribbean, Mediterranean, Southeast Pacific and Northeast Pacific. In the future, a better system based, for example, on the Large Marine Ecosystem (LME) concept (see Sherman and Laughlin 1992) may become available.

The CNPPA regional priorities for establishing or strengthening marine protected areas are limited to the dozen or so actions needed to conserve a representative

sample of all biogeographic zones within a regional network of MPAs. National priorities for new and strengthened MPAs are generally more numerous, depending on how comprehensive existing national MPA systems are. These areas have been mapped on a GIS database of the 18 marine regions by the World Conservation Monitoring Centre and will be available to any interested users.

The World Bank, which supported the CNPPA project, hopes to begin collaborating with governments, other bilateral and multilateral donor agencies, and NGOs to implement regional and national MPA projects. Eventually, these efforts will lead to the development of a globally representative network of MPAs as envisioned in the CNPPA report.

Although governments and donors are investing more in priority-setting efforts, it is not clear to what extent the resulting priorities influence decisions about where to invest resources in conservation and sustainable use activities. The MacArthur Foundation has invested US\$60 million since 1988 in biodiversity conservation programmes in eight priority geographic areas based largely on the Myers (1988) biodiversity hotspots (MacArthur Foundation 1995). Most private foundation donors, however, do not appear to use systematically derived priorities to allocate financial resources. Support by governments and bilateral and multilateral donors for geographic priority-setting is just beginning (see, for example, WCMC 1994; WWF 1994; Rojas and Valejo 1994; BSP *et al.* 1995). This support may signal that donors and governments are prepared to use well-established priorities to guide their activities and funding. However, the limited and recent experience with priorities thus far makes this difficult to assess.

13.2.7 Principles for geographic priority-setting

The most effective actions to conserve biodiversity will take place at the national, and even more so at the local, level. National and local capacities for the conservation and sustainable use of biodiversity are limited everywhere, especially in developing countries. Given these constraints, setting priorities at the national and local levels will have the greatest effect and should help influence and strengthen priorities set from an international perspective, increasing the use of international support resources. Priorities set at these levels are indispensable because they are more likely to:

- focus on specific conservation and sustainable-use objectives;
- specify species, ecosystems or sites;
- reflect national and local values and needs; and
- provide greater opportunity for participation by national and local government agencies, NGOs and communities.

The links between nationally and locally set priorities and actions on the ground are more direct than links between international priorities and site-specific management actions. Nationally determined priorities also indicate to international donor agencies and conservation organizations which ecosystems, habitats and species are considered most important from a national perspective, some of which may also be of international significance (e.g. potential World Heritage Sites, RAMSAR sites, biosphere reserves, etc.). In any case, most internationally set priorities, such as biodiversity 'hotspots' (Myers 1988, 1990) depend on further elaboration at national and local levels.

Johnson (1995) provides a simple set of principles to guide priority-setting processes for maximum effect (see Box 13.2-3). Several of the principles address the political need for participation and consultation in the priority-setting process. Others address largely technical considerations, and one or two might simply go under the heading of 'common sense'. A more extensive set of principles developed by participants at the 1992 Systematics and Conservation Evaluation Workshop held in London (see Forey *et al.* 1994 for papers presented) is summarized by Sullivan (1992).

Box 13.2-3: Principles for setting biodiversity conservation priorities.

1. Link biodiversity priorities with clear conservation goals and objectives.
2. Use a replicable, transparent process to develop credible priorities.
3. Clarify local, national and global biodiversity conservation priorities.
4. Evaluate the advantages and disadvantages of any chosen priority-setting scheme.
5. Make full use of relevant and available information.
6. Involve those responsible for implementing conservation actions in the priority-setting process.
7. Involve other constituencies, including local communities, in the priority-setting process.
8. Establish a process to revise or reassess priorities at regular intervals.
9. Consider how priorities fit in a policy and institutional context.
10. Link conservation priorities to other planning and policy processes such as national biodiversity strategies and action plans.

Source: Johnson (1995).

13.2.8 Conclusion

Several issues in particular are vital to using priority-setting effectively to support policies and strategies to sustainably use and conserve biodiversity (Johnson 1995). First, explicit objectives are essential both to provide guidance to the priority-setting process and to make clear which elements of biodiversity are included in the priorities and which are not. Second, biodiversity is important everywhere, and biogeographic representation should be an objective of initial efforts to set priorities. Third, the conservation of biodiversity is less a question of biology than of social, economic and political factors. Therefore, while priorities must be scientifically sound, their proponents should consider how priorities can have an impact in the social context in which conservation decisions are made. Fourth, priority setting must become an integral part of national biodiversity strategies, action plans and related policy and planning processes. This will require investing in national capacities to develop and implement comprehensive conservation priorities. At the international level, priority-setting should complement but not supersede nationally and locally determined biodiversity conservation priorities.

Most importantly, successful implementation of conservation priorities ultimately depends on the support of important biodiversity stakeholders – the public, and various government agencies – all of whom have social, economic and political needs they consider at least as important as maintaining biodiversity. The best way to ensure that priority-setting both informs and is informed by the range of actors who influence the fate of biodiversity is to develop an effective process for setting priorities. An effective priority-setting process, notwithstanding its technical integrity, is one that starts with clearly defined conservation goal(s) and objectives, is guided by the widest possible array of relevant information, provides opportunities for a wide range of government, academic, NGO, social and private sector institutions to be consulted or involved, and links priorities to discrete institutions, actions and constituencies.

Although biodiversity conservation priorities are most often intended to lead to the establishment of new protected areas, endangered species programmes, or *ex-situ* conservation programmes, geographically defined priorities can be used in other ways as well. For example, information on species and ecosystem distribution and trends, habitat quality, and human land-use and demographic patterns, could be correlated to land tenure and other policies (e.g. tax, agricultural subsidies, etc.) that contribute to ecological degradation. This would allow priority-setters to identify specific policy reforms that could help to sustainably use and conserve biodiversity outside traditional protected areas.

Similarly, cultural/demographic/land-use data (in conjunction with species and ecosystem information) could

be used to identify biologically important areas where people use natural resources in ways that are relatively compatible with biodiversity conservation. Strategies could then be developed to encourage the preservation of such land uses and protect them from rapid and ecologically destructive change.

There is no single formula for developing effective biodiversity conservation priorities. The process of setting priorities will vary between countries according to available information, local perceptions and development objectives. Priority-setting will increase in sophistication and more effective approaches and processes will emerge in the coming years. However, as WCMC (1994) notes, 'For most countries and the world as a whole. . . there is sufficient information on species richness and endemism to allow realistic decisions to be made on where these attributes are likely to be most pronounced, and where investment in safeguarding them would be most effective'. Priority-setting and revising earlier priorities will be a recurrent activity, not a one-time event. Therefore investments in building the information base, making appropriate technologies available (e.g. computer mapping and databases), defining participatory mechanisms, and training, will have long-term value and contribute significantly to the conservation and sustainable use of biodiversity, particularly if policy makers and donors pay attention.

13.3 Measures for sustainable use of biodiversity in natural resource management

13.3.1 Introduction

Human uses of biological resources, as discussed in Section 11, generally lead to the simplification of ecological systems and reduced biodiversity. Measures to maintain biodiversity, as a result, have frequently emphasized the separation of ecosystems, species and genetic resources from most human activities (e.g. establishment of protected areas, prohibitions on the harvesting of endangered species, preservation of germplasm in seed banks or cryogenic storage, etc.). However, it is simply not possible, nor in many cases desirable, to shield all genes, species and ecosystems from human influence. Human impacts have become part of the natural selection process and some components of biodiversity – agricultural genetic diversity, for example – owe their existence to human influence and manipulation.

Humans manipulate approximately 70% of the world's temperate and tropical ecosystems to produce 98% of their food and all of their wood products, according to Pimentel *et al.* (1992b), and only 5% of the temperate and tropical land area is totally uninhabited and unmanaged. Most terrestrial species, therefore, are found in the land area that is managed for agriculture, forestry and human settlements: in Germany, for example, only 35–40% of native species are found in protected areas (RSU 1985). Coastal and marine biodiversity is likewise predominantly found in areas where fishing and other human activities take place, albeit with less intensity and permanence than on land.

Therefore, maintaining biodiversity will depend on measures to use its components sustainably and to manage natural resources in ways that minimize adverse impacts on biodiversity. This chapter assesses methods that maintain biodiversity within the context of the human uses and management of natural resources including, among others, agriculture, forestry, fisheries, urban development and tourism. These measures take place within resource management systems in which the primary objectives are to use natural resources for human consumption and benefit, not the preservation of biodiversity *per se*. Measures in management systems where the principal objective is to preserve and restore biodiversity are presented in 13.4.

13.3.2 Managing biodiversity in agriculture

Agriculture – broadly defined to include cultivation of annual and perennial crops, animal husbandry, and grazing of domesticated livestock – depends on biodiversity for productivity and innovation. Plant and animal breeding, drawing on the genetic diversity of a handful of species in a variety of ecosystems, has enabled humans to develop thousands of domesticated varieties adapted to a wide range of environmental conditions and uses. Agricultural improvements, many of them based on the use and manipulation of biodiversity, have been the driving force behind human population growth and demographic change. And while agriculture has benefited enormously from biodiversity, its success has contributed increasingly to the loss of biodiversity. Land use for human food production now occupies over one-third of the world's land area – in 1991 cropland covered 11% of the world's land area, and permanent pasture 26% – and is the leading cause of habitat conversion on a global basis (WRI 1994).

Meeting the demands of an increasing world population and simultaneously maintaining biodiversity is an enormous challenge. To do so requires measures that:

1. conserve the genetic diversity found in existing domesticated plant and animal varieties and their related wild species;
2. identify and use wild species and genetic diversity to improve agricultural productivity and adaptability in the face of environmental change; and
3. minimize the adverse impacts of agricultural practices on agroecosystems and natural ecosystems.

Traditional and small-scale agriculture, especially in developing countries, is a major repository of agricultural genetic resources, and small farmers have played a major role as stewards of this legacy. Although small farmers have increasingly adopted relatively uniform modern high-yield crop varieties (HYVs), measures to use and maintain genetic diversity are still prominent in many traditional

agricultural systems, as discussed in 13.3.2.1. However, measures to use and conserve biodiversity sustainably within the context of large-scale/modern agricultural systems, as discussed in 13.3.2.2, will become increasingly important as these systems become more prevalent around the world. Measures to minimize conflicts between agricultural expansion and intensification and natural habitat conservation are presented in 13.3.2.3.

13.3.2.1 Managing biodiversity in traditional agriculture

Most of the world's farmers and most of the world's agricultural genetic diversity (see Figure 13.3-1) are found in developing countries where traditional farming systems are still common in many areas. Even in industrialized countries, traditional agricultural practices survive in some places. One of the distinguishing characteristics of these systems is their high degree of plant diversity in the form of polycultures and/or agro-forestry patterns. Subsistence farmers have traditionally minimized risk by planting several species and varieties of crops to stabilize yields over the long term.

Such practices have also served to promote diet diversity and maximize returns under low levels of external input and limited resources (Bartlett 1980; Altieri 1987). Tropical agro-ecosystems composed of agricultural and fallow fields, complex home gardens and agro-forestry plots commonly contain well over 100 plant species per field, which are used for construction materials, firewood,

tools, medicines, livestock feed and human food (Altieri and Hecht 1990; see also Section 11).

Genetic diversity in domesticated animals is also a common characteristic of traditional agricultural systems (Chacon and Gleissman 1982; Chang 1977).

Many traditional agro-ecosystems are located in major centres of crop diversity such as those first identified by the Russian botanist Vavilov in the 1930s and those more recently documented by Zeven and Zhukovsky (1975) and Harlan (1971). These centres contain most of the genetic diversity associated with major food crops (Prescott-Allen and Prescott-Allen 1983), and traditional agricultural systems in these areas maintain populations of variable and adapted landraces as well as wild and weedy relatives of crops.

For example, in the Andes, farmers cultivate as many as 50 potato varieties in their fields (Brush *et al.* 1981). Similarly, in Thailand and Indonesia, farmers maintain a diversity of rice varieties in their paddies, adapted to a wide range of environmental conditions, and regularly exchange seeds with neighbours (Altieri and Merrick 1987). The resulting genetic diversity heightens resistance to diseases that attack particular strains of the crop, and enables farmers to exploit different microclimates and soil conditions and derive multiple nutritional and other uses from genetic variation within species (Altieri 1987; Plucknett *et al.* 1987).

Many plants within or around traditional cropping systems are wild or weedy relatives of crop plants. Cycles

Figure 13.3-1: Centres of genetic diversity for major crops. (Source: Wilkes 1983.)

of natural hybridization and introgression have often occurred between crops and wild relatives, increasing the variability and the genetic diversity available to farmers. Through the practice of ‘non-clean’ cultivation, whether intentional or unintentional, farmers may increase the gene flow between crops and relatives (‘introgression’). For example, farmers in Mexico allow *teosinte* to remain within or near cornfields, so that when the wind pollinates corn, some natural crosses occur and hybrid plants are produced (Wilkes 1977; Alcorn 1981; Chacon and Gliessman 1982; Brush *et al.* 1986). The extent of introgression between wild relatives and crops, however, is a subject of considerable uncertainty, and genetic investigations (at nuclear and cytoplasmic levels) are needed to resolve these controversies for maize (Benz *et al.* 1990), and probably for other crops as well.

A growing number of scientists have emphasized the need for *in situ* conservation of crop genetic resources and

for protection of the agro-ecosystems in which they occur. This allows for continued, dynamic adaptation of plants to the environment and for traditional management, especially in diversified agricultural areas where crops are often enriched by gene exchanges with wild or weedy relatives in fields or in adjacent natural ecosystems. Maintaining traditional agro-ecosystems and closely associated natural ecosystems is one strategy that can be used to preserve *in situ* repositories of crop germplasm (Altieri 1987; Altieri and Merrick 1987). The UN Food and Agriculture Organization’s agreement on Farmers’ Rights recognizes the important contributions made by traditional farmers to the development and maintenance of agricultural crop diversity, as part of the International Undertaking on Plant Genetic Resources Conservation (see Box 13.3-1).

Basing a rural development strategy on traditional farming, ethno-botanical knowledge, and agro-ecological techniques not only assures continual use and maintenance

Box 13.3-1: The International Undertaking on Plant Genetic Resources.

The International Undertaking on Plant Genetic Resources was adopted by an FAO conference resolution in 1983 as the first comprehensive, international, legally non-binding voluntary agreement concerning plant genetic resources. The undertaking seeks to ‘ensure that plant genetic resources of economic and/or social interest, particularly for agriculture, will be explored, preserved, evaluated and made available for plant breeding and scientific purposes’.

Following the same resolution, the FAO Commission on Plant Genetic Resources was established as a permanent intergovernmental body through which countries monitor the implementation of the International Undertaking and advise FAO on its activities and programmes in the field of plant genetic resources. Currently, 110 countries adhere to the Undertaking and 122 are members of the commission.

Originally, the undertaking was based on ‘the universally accepted principle that plant genetic resources are a heritage of mankind and consequently should be available without restrictions’. This concept has been qualified over the years in order to overcome the reservations to it. It now includes:

- an agreed interpretation which recognizes that plant breeders’ rights (UPOV 1978 Convention) are not inconsistent with the undertaking;
- a recognition of the farmers’ rights concept; and
- a reaffirmation that the concept of the heritage of mankind is subject to the sovereign rights of nations over their genetic resources and that farmers’ rights will be implemented through an international fund for plant genetic resources.

These modifications have led to new qualifications on the principle of ‘unrestricted access’.

Following Resolution 3 of the Nairobi Conference for the Adoption of the Agreed Text of the Convention on Biological Diversity, the above-described Global System for Plant Genetic Resources was identified as the context within which the outstanding issues of the Convention (i.e. access to existing *ex situ* collections and farmers’ rights) should be addressed. The global system consists of a number of elements including the World Information and Early Warning System, the International Network of *Ex-Situ* Collections, and a voluntary International Code of Conduct for Plant Germplasm Collecting and Transfer. In 1993 the FAO conference adopted a resolution to revise the international undertaking and to harmonize it with the Convention on Biological Diversity. This process has begun since then and it is intended to convert the undertaking into a protocol to the Convention that will eventually bring under the convention framework the issues of access on mutually agreed terms to plant genetic resources for food and agriculture and the rights of providers of germplasm through the realization of farmers’ rights.

of valuable genetic resources but also allows for the diversification of peasant subsistence strategies, a crucial issue in areas plagued by economic uncertainty (Clawson 1985; see Figure 13.3-2). By incorporating local crops and other native plant germplasm into the design of self-sustained agro-ecosystems, local genetic diversity is then available to farmers (Chang 1977). In recent years, there has been growing interest in community gene banks as a strategy for conserving and using crop biodiversity (see Box 13.3-2).

Trenbath (1992) and Ramakrishnan (1992) among others suggest that various measures can be effective in maintaining the genetic diversity associated with traditional agricultural systems, some of which are modified and presented below:

- establishing policy incentives (e.g. tax breaks, subsidies) so that farmers will retain some area planted to traditional (often mixed) cultivars, cultivated using traditional techniques where necessary to maintain genetic diversity;
- restricting the promotion of homogenous cultivars and exotic stock types by government and commercial interests when the rapid expansion of such cultivars and stock types is linked to significant genetic erosion and when small-scale farmers do not benefit appreciably from such promotions;
- making research on the benefits and costs of using varying numbers of cultivars and stock breeds within farmers' holdings under various levels of intensification a higher priority at national agricultural research centres;
- building capacity within government and NGO agricultural extension programmes to collect information on the diversity of domesticated genetic material, and to characterize the geographic distribution and rate of change associated with agricultural genetic diversity;
- establishing a cultivar registration system and a monitoring system to warn of impending losses of agricultural genetic resources, perhaps based on a combination of agricultural extension systems and networks of agricultural and rural development NGOs;
- training agricultural extension agents in the values of crop and domesticated animal diversity, including their role in encouraging local farmers to retain local cultivars and breeds, providing education on the value of genetic resources and their internationally recognized rights as owners of genetic resources;
- encouraging farmers to retain uncultivated strips within holdings as habitat for weedy relatives of crop

Figure 13.2-2: Traditional agricultural practices viewed from the perspectives of traditional farmers, ethnoecologists and agroecologists. (Source: Primack 1995.)

Box 13.3-2: Community gene banks.

In many parts of the world, farmers still make extensive use of traditional varieties or landraces. This may occur even when new cultivars are available, enabling farmers to grow varieties that are known to be adapted to particular agro-ecological niches or to meet specific uses for which the improved cultivars are not suited (e.g. Brush 1995). Such landraces are usually maintained by individual farmers, often subject to selection and experimentation and frequently exchanged within and between communities through traditional seed supply systems (Longley and Richards 1993).

Many communities have also developed methods of ensuring that their crop resources are maintained for use in emergencies or after natural disasters. These may take a variety of forms. In some Indian communities, sacred groves serve this purpose; in some Brazilian indigenous groups, individuals (often women) are charged with maintaining a secret resource of planting materials. In Ethiopia, community grain pits may be made in which different crop seeds are stored (Worede and Mekbib 1993).

A criticism of *ex situ* gene banks has been that they are inaccessible to farmers and communities. Designed to conserve the maximum crop diversity in secure conditions for long periods, they have been developed within the formal system and have had as one of their main concerns the provision of genetic resources to professional plant breeders. The formality of the system makes it difficult for local communities to have access to gene bank accessions. At the same time, communities have an interest and need to maintain their own crop resources for traditional farming areas and to obtain new crop germplasm with useful characteristics.

In the last few years, there has been growing interest in community gene banks, which offer a way of providing communities with the genetic resources they need to build on traditional practices and provide a link between ‘formal’ and ‘informal’ sectors. A number of developments are under way. In the Philippines, communities have become involved in the maintenance of traditional sweet potato material and the Zuni peoples in the United States have developed a community gene bank for their own traditional crop types (Nabham 1989).

What may be the most extensive programme of community-based gene banks has been developed in Ethiopia. The Plant Genetic Research Centre in Ethiopia (PGRC/E) has developed close links with farmers over many years, and they have collaborated in the maintenance and multiplication of landraces. Now, as part of a programme of on-farm maintenance of traditional Ethiopian landraces of crops such as barley, teff, lentils and chickpea, funded in part by the Global Environment Facility, a number of community gene banks are planned. They would be of simple construction and based in different regions of the country. They would be managed by the communities in collaboration with PGRC/E and hold local materials and new germplasm of potential interest to the farmers in their own crop-improvement programmes.

Community gene banks developed as a result of grass-roots action by communities and NGOs have the potential to play an increasingly significant role in the conservation and use of crop biodiversity. They can link farmers and communities with national *ex situ* collections, provide additional security for locally adapted materials, and provide a source of such material for on-farm breeding and crop improvement. They can also constitute an effective resource for on-farm maintenance of landraces ensuring that the inevitable changes in individual farmers’ practices are to some extent buffered and that the resources continue to be available to the communities.

- plants – especially in areas known to be centres of origin or diversity for crop plants;
- establishing community seed banks and decentralized breeding programmes;
 - providing farmers with a wider range of genetic diversity, crop varieties and species for their trial and selection;
 - redesigning agro-forestry systems to incorporate ecological insights so that tree species and crop species can be more compatible;
- improving valley-land wet rice cultivation and other land-use systems such as home gardens by using appropriate crop species, transferring indigenous technology from one area to another, and redesigning or updating systems developed on the basis of traditional knowledge;
 - strengthening traditional animal husbandry practices so that more effective recycling of waste between this sub-system and the cropping sub-system will result in more productive and diversified agro-ecosystem diversity;
 - encouraging artisanal skills and products based on natural resources accessible to rural communities.

While traditional agriculture, especially in developing countries, is a major repository of crop genetic resources, traditional agricultural practices and the diverse genetic resources associated with them are disappearing rapidly (Gade 1969; Harlan 1975). Technical constraints, including the lack of well-distributed decentralized agricultural research centres that are linked closely to small farmers, together with scarce funds and human resources, mean that crop genetic diversity associated with traditional agricultural practices will continue to disappear at a rapid rate (Harlan 1987). There is, however, evidence that traditional cultivars and breeds will continue to survive in some areas even without outside funding or technical assistance. Several researchers (e.g. Brush 1991; Smith *et al.* 1992) have documented how small farmers combine planting cash crops for markets with raising traditional cultivars for household or local use.

With the growing realization that the more traditional *ex situ* approaches have serious limitations, *in situ* or 'on farm' conservation of diverse crop resources by custodial farmers has become an important issue in the past 20 years (Altieri and Merrick 1987; Plucknett *et al.* 1987; Hoyt 1988; Lleras 1992; Smith *et al.* 1992).

However, while being considered as the best method of conserving crop genetic resources (Brown 1982; Myers 1983) there are serious limitations to relying solely on traditional practices. Critics point out that proponents do not often spell out how to manage thousands of cultivars and local breeds of livestock (Hawkes 1977; Plucknett *et al.* 1987), and cite the moral problems of pressuring some farmers to grow low-yield land races while others plant commercial varieties. Some propose the use of government subsidies (e.g. Myers 1983; Smith *et al.* 1992), while others suggest that private financing and public and private technical support should be extended to encourage maintenance of traditional cultivars and breeds on working farms (Lleras 1994).

13.3.2.2 Managing biodiversity in modern agriculture

In the industrialized world, traditional agricultural systems and practices have been almost entirely replaced by large-scale, commercial systems (NAS 1972; NAS 1993). These large-scale systems are characterized by the use of high-yielding and genetically relatively homogenous plant cultivars and animal breeds, by large inputs of chemical fertilizers and pesticides, and by relatively little mixing of cultivars and animal breeds in the field (NAS 1993). In many parts of the developing world, large-scale commercial systems are becoming increasingly prevalent as well.

Because new arable land in the developing world will become steadily more scarce, higher yields will require the use of better agronomy dependent on a combination of more fertilizer, ploughing, irrigation, and improved plant

materials. All but the last are agricultural inputs that compete with a wide range of social and economic demands on meagre resources in developing countries (Wilkes 1992). Therefore, breeding for better crop plants and management of genetic resources in both time (gene banks) and space (crop-variety mosaics) will be the focal point around which most strategies to increase crop yields will develop (Wilkes 1992). Increased yield from the present cultivated land will reduce pressures to expand agricultural areas.

Ironically, as the human population has grown over the last 2000 years, and especially since the development of the science of genetics at the beginning of this century, we have depended on an increasingly shorter list of crops (Prescott-Allen and Prescott-Allen 1990). Although innovations in modern farming systems have greatly increased agricultural productivity, the biological support system that feeds humanity has narrowed. Driven by international market forces and reinforced by specifications of marketing organizations, supermarket chains, and even officials concerned with animal and crop health, farmers are under continuing pressure to narrow the spectra of crops and livestock they produce.

Four crops – wheat, rice, maize and potatoes – alone account for half of the calories consumed by humans (Prescott-Allen and Prescott-Allen 1990). The most productive and most easily stored/shipped plants (e.g. wheat, rice, maize, orange, apple, banana, etc.) dominate large-scale agricultural systems, and two dozen crops account for approximately 90% of the plant calories consumed by humans (Harlan 1975a). Today, a much-narrowed short-list of about 150 plant species with about a quarter of a million local races are critical to the food supply (Wilkes 1983). *Ex situ* and *in situ* conservation measures in agriculture should be focused on the sustainable management of this short-list (Altieri *et al.* 1987; Hoyt 1988; Wilkes 1989, 1991; Holden *et al.* 1993).

Measures to maintain or expand the diversity of those crops and animals used in modern agricultural systems are critical for several reasons. First, elite germplasm (in the form of high-yielding crops and breeds) has been adopted around the world. Both developed and developing nations are equally subject to genetic vulnerability, since essentially the same hybrids and high-yielding varieties have come to dominate the landscape within the last decade (NAS 1993). Second, these varieties need to be replaced on a frequent basis because pests and pathogens evolve quickly to exploit the new varieties (NAS 1993). To sustain present productivity in modern agriculture we require continued access to germplasm collections and reserve pools of germplasm to back up existing varieties (Duvick 1986), along with development of high-yield crop mixtures or multilines as an alternative to genetic uniformity and monocultures (Wolf 1986; Wilkes 1992).

Global food security is as good as the genetic base we conserve. Three categories of measures exist to preserve the genetic foundation of agriculture. The first is the protection of large tracts of natural ecosystems that contain (or might contain) wild relatives of important crop and domesticated animal species. In the second category are on-farm or *in situ* measures to use and protect rare or threatened cultivars and breeds and/or wild relatives of crop species. The third category consists of *ex situ* measures for the storage and maintenance of agriculturally relevant germplasm (Wilkes 1983; Plucknett *et al.* 1987; Brown *et al.* 1989).

In the first category, large tracts of natural habitats, including their populations of animals and plants, are preserved or managed principally for conservation objectives. In most cases, large-scale ecosystem protection will have little impact on the genetic resources of cultivated plants. The exceptions, however, can be important. For example, MAB (Man and the Biosphere) Reserves have sometimes been purposefully selected and planned to include important agricultural genetic resources in the form of wild relatives of major crop species and traditional cultivars. The Sierra de Manantlán Biosphere Reserve in Jalisco, Mexico, protects wild relatives of both maize and beans (Benz *et al.* 1990). The reserve also protects the fields and traditional agricultural practices of indigenous Indian cultivators from encroachment (Guzman and Iltis 1991; Wilkes 1993a; see 13.4.2 for more information on measures for protected areas). Agriculture has tended to assume that wild relatives will be maintained by nature in wild habitats. This is ceasing to be the case in many areas, and agricultural interests will need to become more directly involved in identifying habitat conservation priorities (see 13.2) and contributing to the implementation of protection and sustainable use measures in priority areas (see 13.4).

In the second category, on-farm conservation, landraces and wild relatives are preserved in selected small areas, along with the genetic diversity generated where the two hybridize. These are evolutionary systems that are very difficult to simulate for plant breeding, and they should not be knowingly destroyed (Brush 1991; Wilkes 1991). Their long-term preservation may not be possible, but their disappearance can be slowed by monitoring and intervention measures (such as fencing) targeted at specific populations. This will allow more time for researchers to understand how these systems evolved. Considerable potential for creative institutional arrangements, as presented in 13.3.2.1 exist for village-level, small area, *in situ* preservation, especially in developing countries (Wilkes 1993b).

In the third category, *ex situ* measures are used for long-term storage of genetic materials, especially for cultivars, breeds, and wild relatives that are unlikely to persist on-farm or *in situ*. Gene banks have been the mode of

preservation for most crop genetic resources (Cohen *et al.* 1991; Holden *et al.* 1993). Gene banks and other forms of *ex situ* protection measures are more fully discussed in 13.4.4 and in Section 8.

Additional plant breeders are needed world-wide to build more diversity into the genetic resources of the world's most important crop and domesticated animal species. There are fewer practising plant breeders now than in the 1950s when the human population was half what it is today (Wilkes 1989; Collin and Phillips 1991). New areas of molecular genetics and biotechnology have attracted researchers and have been responsible, in part, for this decline. In addition, the role of gene banks has not been appreciated by the conservation community. At the same time, the agronomy community has not presented a strong case for the public support of plant genetic resource conservation. Following the yield leaps of the Green Revolution of the late 1960s, most of our plant breeding has been maintenance breeding to keep the yield close to the high levels achieved earlier (NAS 1993).

Genetic uniformity has been created as breeders have developed crops that have (1) rapid and uniform germination of seeds; (2) nearly simultaneous flowering; (3) nearly simultaneous maturation of harvest; (4) stature that promotes mechanical harvest; (5) product uniformity for taste and chemical composition, and (6) year-to-year stability of yield. Genetic changes, mutations, and new recombinations are always taking place in populations of pathogens and if a new genetic combination is virulent on a previously resistant plant host, it will spread across the entire host population if the latter is genetically uniform. With landraces, such genetic uniformity seldom extends beyond the fields of a single farmer or the fields of a village or district. With commercial seed, the uniformity may extend across nations and beyond (Wilkes 1993b).

Commercial agriculture needs a more diverse genetic mosaic of species to reduce genetic vulnerability within and between crops. Planting a crop in smaller blocks mixed with blocks of other crop species instead of planting one crop over large contiguous areas and/or planting several varieties of the same crop in mixed blocks over an area could create mosaics that would overcome some of the genetic vulnerability inherent in the use of uniform elite germplasm.

Positive actions to deal with genetic erosion, genetic vulnerability and the gene banks crisis involve the following initiatives (Wilkes 1992; NAS 1993):

1. New programmes to assess genetic erosion and vulnerability and to monitor the use and geographic distribution of elite germplasm.
2. The development (especially in the public sector) of totally new gene pools to act as genes in reserve to support the commercial breeder with alternatives.

3. Increases in training for the maintenance of plant genetic resources and the building of bridges to the greater conservation community. Genetic resources programmes should be engaged in pre-breeding and moving genes from the collections into enhanced materials.
4. More basic and applied research in order to more efficiently and effectively measure genetic distance between varieties, and improve evaluation techniques, especially those relating to the nature of resistance to pest and pathogens and pest–host interactions, in conjunction with early detection of changes in the virulence of pest and pathogens as well as shifts in the varietal picture.
5. Promotion of education to inform the food industry, farmers, seedsmen, plant breeders and others about the relationship of genetic and spatial diversity with regard to the potential for crop vulnerability and failure so that they can develop alternative management strategies to genetic uniformity. Such methods include parallel breeding, genes in reserve, enhancement breeding for gene pools, wide crosses, biotechnology and alternatives to monocultures such as crop rotation, crop mixtures, multiline resistance, pyramided resistance factors, manipulations of pest parasites, pest-trap crops, insecticides/fungicides and better monitoring.

Innovative new forms of support for such activities may be needed since national and international public financing for agricultural genetic resources conservation may actually be declining. Research taxes or other forms of compensation paid by large seed firms, agribusinesses and other large commercial interests that use genetic resources from local farmers or publicly maintained seed banks are one option to involve the private sector more fully in conservation activities from which they benefit, but for which they do not currently pay.

Because of its major role in ensuring global food security, the conservation and utilization of crop plant genetic resources have become major concerns of international efforts such as the FAO Commission on Plant Genetic Resources and the Consultative Group on International Agricultural Research. The unique utility aspect of crop plant conservation has not generally been understood and these genetic resources have been poorly supported and managed (NAS 1993). Genetic erosion and the short-term benefits gained from the use of elite germplasm have created the potential for genetic vulnerability in the long term (NAS 1993). When societies are no longer able to breed crops that can respond to and effectively meet changing conditions, they have lost the key to agricultural sustainability. It will be the positive

responses of crops to agricultural practices, pests, pathogens and social institutions that will determine the success of our attempts to feed ourselves and yet maintain agricultural systems that are sustainable (Wilkes 1992).

13.3.2.3 *Managing agricultural impacts on natural resources*

As well as practices to use and protect agricultural genetic resources as presented above (13.3.2.1 and 13.3.2.2), methods are also needed to ameliorate the negative environmental effects of agricultural practices on the natural resource base that sustains food production and the biodiversity of other ecosystems. Soil erosion, reduced diversity of invertebrates and soil microfauna, water contamination and depletion, and conversion of natural habitats are associated with agriculture in most temperate and tropical areas (see Section 11).

Around the world, degradation of agricultural land by erosion, salinization and waterlogging causes the irreversible loss of an estimated 6 million hectares each year (Pimentel 1993). While no systematic evaluation of the overall global status of human-induced soil degradation has been made, Tolba *et al.* (1992) conservatively estimate that 25% of agricultural land is affected by soil degradation. Soil loss rates in Europe and the United States range between 10 and 20 tonnes per hectare per year. In Asia, Africa and South America, cropland soil erosion ranges between 20 and 40 tonnes per ha per year (Pimentel *et al.* 1993). Erosion adversely impacts food production by reducing water availability, nutrients (e.g. N, P, K and Ca), and organic matter, and by restricting rooting depth as topsoil thins (El Swaify 1985). Annual food production losses as a result of land degradation may exceed 12 million tonnes of grain (FAO 1991b). Agricultural soil degradation, in addition to reducing crop productivity, contributes substantially to the degradation of other habitats and the loss of biodiversity. As much as 80% of the 11.6 million hectares of forest cleared annually is for agriculture, and Pimentel (1993) estimates that most of this conversion is to compensate for degraded agricultural lands. Sediments from erosion fill river beds, lakes and estuaries, and settle on nearshore coastal marine environments. This interferes with fish breeding, smothers coral, and accelerates the eutrophication of aquatic systems as nutrients associated with eroding soils enter the environment.

A variety of conservation technologies are available to minimize soil erosion. Most technologies are based on the principle that soil erosion and rapid water runoff can best be controlled by maintaining adequate vegetation cover. Depending on soils, slopes, crops and climate, soil conservation technologies include contour planting, strip cropping, crop rotations, terraces, mulches, no-till planting, ridge planting, grass strips, tree/shrub hedges,

agro-forestry, shelter-belts, and various combinations of these technologies. Matching the most effective technologies with specific soils, climates and topographies is a high priority area for future research (Pimentel 1993).

Agrochemicals (fertilizers, herbicides and pesticides) also have tremendous impacts on biodiversity. Fertilizers cause eutrophication in rivers, lakes and coastal areas as nitrate and phosphorus enrich aquatic environments. This leads to dense algal blooms, dramatically increasing biological oxygen demand and creating lethal conditions for many fish, invertebrates, plants and other forms of aquatic life.

While pesticide use world-wide is estimated to increase crop productivity by approximately 10% (Pimentel *et al.* 1992a), the abuse of these chemicals imposes enormous environmental costs and may limit agricultural gains. Pimentel and Levitan (1986) estimate that 90% of pesticides do not reach their target pests and instead contaminate land, water and air. Pesticides kill beneficial natural predators of agricultural pests, reduce microbial diversity associated with soil productivity, and harm humans, fish, birds and other wildlife. Pimentel *et al.* (1992a) conservatively estimate that the improper use of pesticides in the United States alone causes the death of at least 67 million wild birds, 14 million game fish, and unknown numbers of mammals, amphibians, reptiles and invertebrates each year.

Excessive use of pesticides also has adverse impacts on agriculture itself. Pimentel *et al.* (1992) estimate that the annual cost of pesticide losses in agriculture due to pesticide resistance in crop pathogens, loss of natural enemies of agricultural pests, honeybee and pollination losses, and crop and livestock losses from pesticide contamination, is at least US\$3 billion. Perhaps the most damaging losses come from the loss of soil invertebrates and micro-organisms essential to the structure and function of the soil. However, estimates cannot be made for these losses because no relevant quantitative data have been collected. World-wide, the growth of pesticide sales have been accompanied by growing resistance of pest species to pesticide use (Lean *et al.* 1990; see Figure 13.3-3). The proportion of crop losses in the United States due to insects has nearly doubled in 40 years despite a tenfold increase in the amount and toxicity of insecticides used (Pimentel *et al.* 1991b). Much of this is due to increased resistance of pests to insecticides, but other factors such as the increased use of monocultures, destruction of natural predators, and reduced use of crop rotations are involved as well.

Integrated pest management (IPM) and other strategies have been developed to address problems arising from pesticide use. IPM strategies may include the selective use of pesticides, greater use of biological controls (e.g. natural or introduced predators of pests), genetic resistance, and

Figure 13.3-3: Dramatic world-wide growth in pesticide use since 1970 has been accompanied by pesticide resistance in a growing number of pest species. (Source: Lean *et al.* 1990.)

other management practices such as greater crop rotation and the use of varied planting, harvesting and irrigating schedules (Fulick and Fulick 1991). In Indonesia, the government introduced a large-scale IPM programme for subsidies on those that remained. A nationwide programme was established to show farmers how to conserve natural predators such as spiders, with spraying as a last resort. Within three years, farmers were using 90% less pesticide, rice yields were increasing, and less harm was being done

to the environment and biodiversity (Fulick and Fulick 1991). With training programmes and upgraded extension systems, other Asian countries have achieved varying degrees of success with IPM (Kenmore *et al.* 1987).

Actions to restrict the impact of agriculture on biodiversity include the following:

- supporting research and policies that encourage use of integrated pest management in order to protect wildlife and natural enemies of crop pests from damage by unnecessary spraying;
- avoiding dispersal of fertilizers and herbicides onto any relatively undisturbed habitat adjacent to agricultural fields, especially those adjacent to streams, rivers, lakes and wetlands;
- training extension agents to work with farmers in developing natural habitat conservation strategies;
- leaving some relatively undisturbed habitat on holdings to maintain overall biotic diversity, including wild species beneficial to agriculture;
- using native woody species when establishing wind-breaks or woodlots to check wind and water erosion of soil and nutrients on agricultural holdings;
- where agricultural expansion is inevitable, promoting the establishment of land-use planning policies and practices that direct expansion to areas where cultivation and grazing can be practised sustainably (i.e. areas where climate, soil, markets and infrastructure are suitable for long-term agriculture) and where unique biodiversity resources are not located.

13.3.3 Managing biodiversity in forestry

As with agriculture, the relationship between forestry and biodiversity is strong. Although the 'variety of life in the infrastructure of forests is immense, fragile, and still very poorly understood,' Wilson (1993) writes that enough is known to conclude that 'biodiversity is vital to healthy forests, while proper forest management is vital to the maintenance of biodiversity'.

This relationship was known, at least intuitively, to many traditional cultures around the world. Community forestry's roots pre-date the emergence of agricultural society (Johnson and Cabarle 1993). Traditional practices in community forestry encompass a wide range of forms including agro-forestry, sacred groves, forest gardens, collection of non-timber forest products, and highly selective timber felling, among others. Many of these forms include measures that maintain or even enhance

biodiversity. Although many measures for the sustainable use and management of biodiversity in traditional forestry systems are, like their counterparts in agriculture, rapidly disappearing, others are finding new roles in strategies to sustain forest resources. The role of measures to sustainably use and manage biodiversity in traditional forest management is presented in 13.3.3.1.

Modern silviculture, based on forestry systems first developed in Europe during the nineteenth century, has focused on timber productivity – often at the expense of biodiversity. In recent decades, ecology and other forest-related sciences have documented the links between forestry, ecosystem processes and biodiversity. Forestry around the world is undergoing a transformation as new measures are developed to maintain biodiversity within the practice of forestry (Aplet *et al.* 1993). Measures being used in large-scale forestry to manage and sustainably use biodiversity are presented in 13.3.3.2.

13.3.3.1 Managing biodiversity in traditional forestry

Research in many forest areas previously thought to be relatively pristine and unmanaged, particularly in the humid tropics, has yielded some striking results. The natural forests in many – even most – tropical areas today increasingly appear to be the product of human intervention, selection and management (Gómez-Pompa and Bainbridge 1991). Before European settlement, the species and ecological diversity in some forest areas in North America were also manipulated by native peoples (MacLeery 1992). Traditional forest management practices, where they still survive, remain important measures for maintaining and sustainably using biodiversity (see Section 11). The knowledge provided by these practices, and those that were dropped as cultures changed or disappeared, also provides lessons that may help modern forest management to become more sustainable in coming decades.

Agro-forestry – combining trees that provide food, fibre, fodder, medicine, and building materials with annual and perennial crops and livestock – is at the centre of most traditional forest management systems. In the Maya region of southern Mexico and Central America, agro-forestry consists of the selection, cultivation, introduction and protection of trees throughout the landscape. In present-day Maya towns, as many as 60 to 80 tree species can be found in an individual forest garden and as many as 200 species in a village (Herrera Castro 1990). These trees are used for building materials, firewood, food, medicine and fodder. Many of the trees are the same species found in nearby natural forest areas, while introduced species such as guava, banana, lemon, orange and other citrus species are also used. Gómez-Pompa *et al.* (1993) estimate that these forest gardens cover more than 25 000 hectares in the Yucatán, or approximately 10% of the region's forested area.

Trees are used in a multitude of other ways as well. Along the edges of or scattered in agricultural fields, an abundance of native nitrogen-fixing tree species and varieties, probably reflecting centuries of human selection and protection, are used to maintain soil fertility (Flores Guido 1987). Individual trees are selected and protected in *milpas* or clearings for crop production created in a shifting cultivation system, a practice thought to account for the high species diversity found in secondary forests on fallow lands. Leguminous trees are used as shade trees for cacao and coffee, a practice that lowers annual yield but extends the useful life of crop plants (Gómez-Pompa *et al.* 1993).

Natural forests are protected along trail networks, edges of *milpas*, and other areas. Strips of forest left along trails provide valued shade for travel, while belts of forest near *milpas* probably play an important role in regeneration on fallow lands (Gómez-Pompa and Bainbridge 1991). These forest belts undoubtedly provide habitat for many forest species and corridors for mammals and birds between larger natural forest areas.

Similar integrated traditional forest management systems are well documented in many other tropical regions, including the islands of Java, Sumatra and Borneo (Soemarwoto and Soemarwoto 1984; Michon *et al.* 1986; Padoch and Peters 1993), peninsular Malaysia (Whitmore 1975), the Catatumbo region of Colombia (Pinton 1985), Brazilian Amazonia (Posey 1984) and many other areas (see Alcorn 1990 for review). There are many examples of measures used in other systems.

- Dislodging grasses, preventing fires, and ringweeding pioneer species are techniques being used by local communities to regenerate deforested areas in the Philippines (Nasol 1994).
- Cultural beliefs, such as the conviction of the Kayapo in Brazil that old abandoned fields are full of spirits and should be avoided, or that medicinal plants can only be harvested by the medicine man, can, in effect, restrict over-exploitation of forest resources (Posey 1993).
- Many indigenous peoples exchange and spread useful species to forest openings, fallow fields and within forests to increase food diversity and the availability of other products – practices that probably increase overall biodiversity levels (Posey 1993).
- Planting of species attractive to game animals has, when the field is left because products are too high to harvest, assured that game animals will still be available (Posey 1993).
- Reliance upon older fields as sources of cultivars has been encouraged (Posey 1993).

Natural forest management – often defined by foresters as the controlled and regulated harvest of timber species in natural forests – has gained considerable attention as one of the most promising strategies for slowing tropical deforestation. In general, however, natural forest management has so far failed to live up to its potential for sustaining humid tropical forests (Poore *et al.* 1989). Many of the most promising initiatives in natural forest management are community-based and controlled (Poffenberger 1990; Perl *et al.* 1991). Most community-based natural forest management systems use the same silvicultural techniques that are used in natural forest management practices on concessions or on private lands (e.g. minimum diameter limits, selective harvesting, and either monocyclic rotations or multiple-entry polycyclic regimes). However, community-based systems are much more likely to integrate non-timber product harvesting, to use or market lesser-known tree species, and to impose seasonal or area restrictions on harvests to protect soil and water quality and protect wildlife (Johnson and Cabarle 1993).

While most community-based natural forest management projects are relatively recent in origin (most started in the 1980s and 1990s), there is indirect evidence to suggest that they are more sustainable and less damaging for wildlife than large-scale commercial operations. Several assessments (Buschbacher 1990; Uhl *et al.* 1990; Perl *et al.* 1991; Johnson and Cabarle 1993) of sustainability in natural forest management conclude that small-scale, community-controlled operations have generally demonstrated fewer adverse impacts on forest ecosystems than have large-scale commercial operations.

The advantages of local control include better policing and husbanding of local forest resources and a more equitable distribution of benefits. Closely knit communities deeply tied to the land they own tend to be committed to sustainability and to weather the vagaries of fluctuating markets and socio-political change with remarkable grace. Then, too, programmes designed to encourage community forestry generally cost less than government management of public lands – and often work better (Johnson and Cabarle 1993).

There are, however, problems and uncertainties with community forest management. Not all communities are equipped politically, financially and technically to manage extensive forest tracts. Many forests are remote from markets and services. Often, local land claims are not recognized by governments and are disregarded by outsiders. Few state forestry agencies and donors provide the short- or long-term investment needed to develop local capacity. Most investors prefer highly technical and capital-intensive forest operations that yield a quick return: these operations, however, lie outside the reach or interest

of community groups. Perhaps most important, national economic and development policies – especially in agriculture, energy, trade and finance – are often dictated by global market forces that encourage short-term profit-taking, which promotes land-use practices that endanger forests and local communities (Cabarle 1991; Colchester 1991).

Today, traditional systems of forest management are being joined with technical assistance provided by government forestry agencies (Poffenberger and McGean 1994). These joint management programmes, especially in parts of Asia, do not seek to replace traditional forest practices but to augment them with help in forest management planning, silvicultural practices, and marketing (see Box 13.3-3; also 13.5.2.4). In most cases, successful joint management requires a significant transfer of responsibility from state agencies to villagers (see also 13.6.2).

13.3.3.2 Managing biodiversity in commercial forestry

Large-scale commercial forest management is widely practised today in tropical, temperate and boreal forests. Logging practices in these systems have often been criticized for their adverse impacts on biodiversity and on other non-timber resources found in forest ecosystems (e.g.

Uhl and Viera 1989; Johns 1992; Whitmore and Sayer 1992; Noss 1993). A range of measures, however, is available for the protection and sustainable use of biodiversity in commercial forestry. First, long-term sustainable forestry depends on measures to maintain the genetic diversity of forest trees so that forestry can respond to environmental changes (e.g. climate change) and biological changes (e.g. new pathogens or pests). Second, measures can be taken to minimize the impacts of logging on biodiversity and ecological processes. Third, biodiversity inventory and monitoring are vital tools (see Section 7) for adaptive management techniques that seek not only to produce fibre but also to maintain biodiversity and ecosystem services as well.

13.3.3.2.1 Measures for the sustainable use and management of forest genetic resources. The genetic diversity of some forest trees, especially those highly valued for timber, is being narrowed as tree populations are heavily impacted by intensive logging and natural forest ecosystems are converted to plantations or other uses. A review of the conservation status of forest trees by the US National Research Council (NRC 1991) concluded that nearly 500 temperate and tropical species are endangered (using IUCN guidelines), either world-wide or at least in

Box 13.3-3: Joint forest management in India.

In many parts of the world, traditional forms of forest management have been replaced by timber-orientated commodity production forestry. Often, this transformation has depleted forest species and left local communities with fewer resources to supply food, clothing, shelter and basic subsistence needs. For 125 years, Indian forest management policies emphasized state custody of forest resources, the development of plantations, and timber production from natural forests. These policies often failed to meet the needs of local communities and were biologically unsustainable. In the past 20 years, however, state forestry authorities and local communities have collaborated on the development of Joint Forest Management projects to meet demands on forest resources.

Before the advent of joint forest management policies in India, extensive areas of natural forest were being converted into plantation forests and deforestation rates approached 1.5 million hectares per year. Despite provisions in the 1980 Forest Conservation Act that restricted the felling of natural forests and emphasized the potential of non-timber forest products, high deforestation rates continued. In addition to being targets for the growing demand for commercial wood products, the forests were also under growing pressure from the 56 million people living in or around forests to supply daily needs. The custodial practices for forest preservation exercised by the state were no longer effective in controlling such demands.

In West Bengal, foresters realized that the future of *sal coppice* forests – once a major economic resource – was linked to local community participation in forest management and benefit sharing. Local communities were invited by the state to become partners in protecting natural forest land and aiding natural regeneration, for which they would receive harvesting rights to fuelwood and non-timber forest products (e.g. fruits, nuts, medicinal plants) and a 25% share of timber sale profits (SPWD 1992). The response was slow at first, but by the late 1980s, many communities throughout West Bengal were involved in Joint Forest Management projects.

Communities are now actively protecting and managing forest lands, deforestation rates have declined, and conditions for wildlife and biodiversity are improving. Convinced by the success of Joint Forest Management projects in West Bengal and elsewhere, India issued guidelines in 1990 to encourage all states to adopt Joint Forest Management procedures. There are now nearly 10 000 forest protection committees, responsible for the management of 2 million hectares of forest in ten Indian states.

significant portions of their ranges. Future forest productivity in the face of environmental change will, as with agriculture, depend on managing and using the genetic resources of forest trees.

The management of forest genetic resources lags behind that of agricultural genetic resources. The genetic architecture of forest trees is poorly understood, breeding is slow, and wide variations in physical, ecological and economic environments are factors to be considered in the use of available genetic variation (NRC 1991). A forest genetic resources group convened by the US National Research Council in the late 1980s (NRC 1991) concluded that 'no adequate global strategy exists for systematically identifying, sampling, testing and breeding trees with potential use'. The development of improved varieties of tree species for use in agriculture, rehabilitation of degraded lands, and industry has been given little attention: there is not even a unified list of trees with high potential for use. Such a list, according to the group, should contain at least double the 400 tree species known to have been tested or included in breeding programmes and should include at least ten times as many tropical species in breeding programmes. In particular, genetic resource conservation programmes are needed for species that are not found in reserves or protected areas, especially in the tropics.

The value of *ex situ* genetic conservation is limited by a number of factors in combination: naturally high levels of genetic diversity, the predominance of out-crossing breeding systems, long generation times, frequently low viability of stored propagules, and temporally and spatially variable environments. Strategies to counter genetic losses start with good silvicultural practices which avoid high-grading (cutting the largest or best specimens) or leave relatively undisturbed genetic reserves in production forest areas. Other strategies include collecting seeds and pollen for *ex situ* preservation in seed banks, establishing seed orchards, and increasing the genetic diversity of plantations. Ultimately, the most effective strategy is *in situ* preservation of natural forest stands large enough to maintain themselves through natural regeneration and to encompass natural disturbance events (e.g. fire) as well as other ecological processes and biotic interactions (i.e. evolutionary forces). Protected area systems therefore provide the best means for genetic conservation (Ledig 1988).

Both *ex situ* and *in situ* preservation will benefit from identifying priority populations to sample or save. Priorities for *ex situ* preservation strategies need to identify which populations and what number and distribution of populations need to be sampled. Effective *in situ* genetic conservation strategies must determine which populations to maintain and the size, distribution, and number of populations required to meet a number of objectives. These objectives include:

1. preserving a representative sample of among- and within-population variation;
2. protecting the genetic integrity of individual populations from genetic contamination (e.g. cross-breeding with genetically uniform plantation stands);
3. maintaining a dynamic equilibrium between inter- and intra-specific competition, including adequate range of age distribution, habitat availability for pollinating and seed-disseminating species, and the breeding system that shapes the species' genetic structure (Ledig 1986).

Similar approaches can be used to identify priority populations for both *ex situ* and *in situ* conservation. Genetic patterns in tree species are often completely unknown or known for only an unrepresentative fraction of a species' population. A common strategy in the absence of information is to preserve or sample populations in representative habitats, since they will probably include a maximum range of the species' genetic variability. Ledig (1986) stresses the importance of sampling marginal habitats where selection may have favoured novel variants.

The ideal strategy is to map geographic patterns of genetic variation over a species range and measure the extent of variability within populations. This, of course, requires good information on population distributions and considerable expense and effort to characterize genetic variability within populations. Technological innovations during the past decade have made surveying genetic variation much more practical, especially for species with small ranges or few populations. Once collected, samples can be characterized by using electrophoretic gel separation of enzymes that provide markers of genetic composition (allozymes) (see Section 2.2).

Genetic analysis can provide information critical to identifying priorities for the conservation of rare or endangered species limited to a handful of populations. For example, only two populations of Torrey pine (*Pinus torreyana*) remain, both of them located in southern California. Although both populations are believed to have lost much of their natural genetic variation, allozyme analysis revealed significant differences in the genetic make-up of the two populations (alleles differed at 8.5% of their gene loci). Therefore, conserving both populations is probably critical to their long-term persistence, especially because of the low level of genetic variability to begin with.

There are some common problems with most genetic resource reserves, irrespective of the objectives of management. Often the reserve size is too small, limiting the effective population size of the target species. Associated with this, distances between adjacent reserves are often large, which can result in problems of isolation and reduced gene flow. Depending on how the surrounding forest is managed, edge effects in small reserves may be so great as to significantly modify the habitat. Even when

conditions are adequate for the targeted species, they may not meet the requirements of mutualistic species, of which there may be many, especially in the tropics, but which are usually much less well understood. Further, smaller reserves maintain fewer animal species, some of which may serve as pollinators, seed dispersers or seed predators, and are essential for plant reproduction.

The NRC working group (NRC 1991) concluded that a global strategy combining *in situ* and *ex situ* methods is needed to conserve tree genetic resources. Their most important recommendations include:

- In situ and ex situ programmes to conserve, manage and use forest tree resources should be expanded to increase the number of species in management programmes at least tenfold.
- Long-term in situ genetic management plans should be developed, especially for tropical and subtropical species.
- Planted forests, or ex situ stands, should be used more often to serve as living seed banks and as test and evaluation stands.
- As a complement to in situ programmes, technologies should be developed and applied for pollen, seed and tissue culture preservation; long-term storage (e.g. cold storage) programmes are needed to back up *in situ* living stand genetic resource programmes.
- More emphasis should be placed on co-operative and co-ordinated exploration, collecting and testing programmes between countries, particularly for species with broad multinational ranges.
- Breeding and testing programmes should at least double the number of species with known potential value.
- Forest genetic resource programmes should conserve more species – especially those not found in effectively managed protected areas – that lack clear present or potential value and those that have little known potential value.
- Dramatically increased efforts are needed for accurate inventories of forest trees world-wide and to research the distribution and structure of genetic variation of forest trees, especially in the tropics.
- Tree genetic-resource management needs should be assessed within broader national forest plans, national biodiversity strategies, and agricultural

development strategies and priority programmes included in the funding and implementation of such programmes.

- A global database on the conservation status of tree genetic resources should be established to augment the limited national databases that exist and the valuable efforts of the FAO Panel of Experts on Forest Genetic Resources.

13.3.3.2 Minimizing the impacts of forestry operations on biodiversity. While commercial logging in temperate and tropical forests rarely leads directly to deforestation, timber harvesting can have devastating impacts on forest ecosystems. Extensive damage to unharvested trees is common in many logging operations. For example, when less than 2% of the trees greater than 10 centimetres in diameter were harvested in an Amazonian floodplain forest, 26% of the remaining trees of equivalent size were seriously damaged or destroyed; forest canopy cover was reduced by 50%; and logging roads exposed 8% of the forest floor (Uhl and Viera 1989). Over time, damaged trees are more susceptible to pathogens (Putz 1993) and undamaged trees become more vulnerable to blow-downs in storms than un-logged forests (Johns 1992). In the temperate hardwood forests of the southeastern United States, evidence suggests that even 50–85 years after clear-cut logging, the herbaceous plant-species diversity of affected areas has yet to recover (Duffy and Meier 1992). The impact of logging on biodiversity, however, has been a contentious issue (see, for example, Elliott and Loftis 1993; Steinbeck 1993).

In both tropical and temperate forests, a growing body of evidence shows that logging disturbances tend to favour an increase in generalist or opportunistic invasive species, while species with specialized mature forest habitat requirements decline or disappear (Isabirye-Basuta and Kasenene 1987; Holloway *et al.* 1992; Thiollay 1992; Niemela *et al.* 1993; Frumhoff 1995). The effects of converting natural forests to plantations are, of course, much more dramatic (see, for example, Showalter and Means 1988). Logging operations can also have severe impacts on aquatic and marine systems. For example, protecting salmon and other anadromous fisheries has created enormous conflicts with forest policy in the northwestern United States and Canada (Barber *et al.* 1994).

The role of disturbances such as fires, hurricanes and wind-throws, and the role of ground debris, standing snags, and clumps of mature trees in regeneration, have been found to be critical in the maintenance of biodiversity and ecosystem integrity (Putz 1987). Foresters have tried to limit the role of natural impacts in forest ecosystems while environmentalists have tried to minimize logging impacts on forest systems.

Around the world, however, forest researchers are seeing evidence that eliminating disturbance can have adverse impacts on both biodiversity and forest productivity. For example, forest-fire suppression programmes and single-tree selection harvesting prescriptions are resulting in major disruptions of ecosystem processes and changes in forest composition from northern temperate pine forests to mahogany forests in the tropics: mahogany species and most pines, for example, require substantial canopy openings for regeneration (Snook 1989; Pfister 1993). Research shows that timber harvesting and silvicultural practices that mimic natural-stand and landscape-level dynamics will provide the best opportunities to maintain biodiversity in natural forest ecosystems (e.g. Hartshorn 1989; Franklin 1993; Noss and Cooperrider 1994).

To minimize the adverse impacts of forestry operations on biodiversity and to maximize the likelihood of sustainable use, timber harvesting methods and silvicultural practices are being developed that mimic natural-stand and landscape-level dynamics (see, for example, Aplet *et al.* 1993). Natural disturbance regimes, such as fire, pathogen outbreaks, wind damage, and other processes critical for maintaining species diversity, are used as models for designing harvesting plans and silvicultural treatments. Such methods can, depending on the forest ecosystem, range from clear-cutting large tracts of forest using heavy equipment to scarify the soil surface, to gently extracting single trees manually, with draft animals, or with an aerial system (e.g. sky-lines or helicopters). Rotation periods can also reflect natural temporal patterns, and stands of different ages (including protected old growth) can be distributed across the landscape in manners that reflect natural spatial patterns (see, for example, Harris 1984; Franklin 1993; Mladenoff *et al.* 1994).

Stand-level management plans in which canopy-tree replacement occurs primarily in small openings created by the death of single trees should include measures designed to assure that this disturbance regime is replicated as closely as possible. Such measures include directional felling and planned extraction of logs along rationally located skid trails and roads. Planning of extraction pathways can greatly reduce both logging damage and logging costs. Where ground-based extraction equipment is employed, the machines should be as small as possible, and logs should be winched for the longest distances possible to reduce the proportion of the area crushed by machinery. Aerial extraction systems, especially sky-line and helicopter yarding, and at-the-stump log processing (e.g. with portable sawmills) can also diminish logging damage.

Many of the deleterious environmental impacts of commercial logging operations are due to secondary effects such as hunting, forest colonization and conversion along logging roads, especially in tropical areas. Responsibility for these effects should be borne, at least to a large extent, by the people who most benefit from

logging. Providing field crews with adequate compensation and supplies so they do not have to hunt for subsistence or earn income by selling wildlife to markets can reduce the deleterious impacts of forestry operations on populations of large mammals and birds in remote tropical forest areas.

More specific measures to maintain biodiversity in areas managed for commercial forest production include:

- Establishing protected area systems, both inside and outside concession areas, that cover (a) representative areas of all forest types, (b) examples of those forests having high species diversity or high levels of endemism, and (c) forest habitats of rare and endangered species or species associations (Budowski 1984; Blockhus *et al.* 1992).
- Leaving larger forest patches with complex shapes and design patches of different successional classes adjacent to each other, thereby maximizing forest interior and landscape interspersions, both of which may facilitate seed dispersal and regeneration (Mladenoff and Pastor 1993).
- Using less intensive harvesting and management practices in forest areas adjacent to protected areas and other sensitive habitats, and in areas that may serve as corridors to nearby protected areas or natural habitat areas (Blockhus *et al.* 1992).
- Using interdisciplinary teams including foresters and economists joined by botanists, zoologists, conservation biologists or other appropriate specialists in plant and animal ecology to develop and monitor the implementation of forest management plans (Blockhus *et al.* 1992).
- Publicizing production forest boundaries, and marking boundaries to prevent harvesting in areas not designated for logging, and to protect genetic resource and habitat reserves designated within production forest areas (Blockhus *et al.* 1992).
- Involving local people, where appropriate, in forest management planning since their knowledge of forest resources and forest ecology can be valuable in developing sustainable forest management systems in commercial forest areas (Blockhus *et al.* 1992).
- Reducing disturbances that do not mimic the natural disturbances in that ecosystem (Blockhus *et al.* 1992).
- Establishing protected riparian forest strips along

rivers, streams, lakes and wetlands. While the size of these will vary according to the ecosystem and the intensity of harvest disturbance, general guidelines suggest these strips should be a minimum of 20 metres wide along perennial streams of less than 20 m width and at least 50 m wide along larger streams, rivers and lakes.

- Increasing uneven-aged management by extending harvest rotation times and aggregate cuts over time, to minimize induced edge effects and fragmentation and increase structural diversity, and leaving behind some dead trees and downed woody debris (Franklin and Forman 1987; Noss 1987; Harris 1984; Hansen *et al.* 1991; see Figure 13.3-4).
- Encouraging directional felling and planned extraction of logs along rationally located skid trails and roads. Planning of extraction pathways can greatly reduce both logging damage and logging costs (d'Silva and Appanah 1993).
- Using natural temporal patterns when considering rotation periods. Stands of different age (including protected old growth) should be distributed across the landscape in ways that reflect natural spatial patterns. Premature cutting should be prohibited and seed trees should be evenly distributed (d'Silva and Appanah 1993).
- Finally, consider using impact studies, registration of natural assets, and environmental audits that can be carried out on commercial forest lands – something that large forestry operations are increasingly using in a number of countries (Pott 1992).

Such guidelines should be viewed as provisional working hypotheses to be tested, revised, prioritized and adapted to region (b) and site-specific ecological conditions. Environmental damage related to logging and forest management activities is all too often excessive because of the lack of any planning and the absence of control over harvesting activities (see, for example, Jonsson and Lindgren 1990; Appanah and Wienland 1991). This continues to be a serious problem in many tropical areas, and occasionally also in temperate areas. Because such guidelines often mean harvesting timber at lower intensities, in smaller areas, or over extended rotation lengths, managing biodiversity in production forests will often be viewed as luxuries by timber producers.

There are, however, encouraging developments that auger well for managing biodiversity in forest production areas. Several international efforts, including the 'Montreal Process' and the 'Helsinki Process' which cover all temperate and boreal forest countries, have developed criteria and indicators for sustainable forest management,

Figure 13.3-4: (a) Conventional clear-cutting methods in the US Pacific Northwest remove all trees from an area on a 70-year cycle, thus reducing the structural diversity and habitat for a wide range of species. (b) Proposed new practices maintain the structural diversity by leaving behind some old trees, standing dead trees, and fallen trees, and increasing rotation lengths. (Source: Hansen *et al.* 1991.)

including the conservation of biodiversity (Sizer 1994). Independent certification of forestry operations as being 'sustainably managed' has grown dramatically in recent years. The Forest Stewardship Council (FSC) has been organized to set minimum standards for independent certification, and the International Standards Organization (ISO) may develop standards for sustainably produced wood products as well. Several principles underlying the FSC accreditation of independent certifiers are relevant to the management of biodiversity (see Box 13.3-4).

13.3.3.2.3 Biodiversity inventory and monitoring. Adaptive management principles (continuous monitoring of key variables and revision of management activities; see 13.1) are essential to maintaining biodiversity in managed forests. Most evidence of the sustainability of natural forest-management systems remains unconvincing (see Johnson and Cabarle 1993). Vague management objectives and a lack of project monitoring undermine its credibility, and most projects do not last long enough to be useful as a basis for judging sustainability. Timber yield and natural regeneration rates are offered as 'evidence' of sustainability because most forest managers do not monitor anything else.

Besides integrating research and monitoring much more fully into their projects, forest managers need to track and monitor a wider range of ecosystem indicators. These could include:

Box 13.3-4: Forest Stewardship Council principles for sustainable forest management.

The Forest Stewardship Council (FSC) was established in 1993 to promote good forest management world-wide, based on a set of principles designed to ensure that all forests are managed in a way that is environmentally responsible, socially beneficial and economically sound. The main objective of the FSC is to link the ‘green consumer’, who may be willing to pay more for sustainably produced wood and wood products, with producers who are seeking to improve their forest management practices, obtain better market access and achieve higher revenues. The idea is to harness market forces to reach specific environmental goals. The FSC’s main functions are to evaluate, accredit and monitor timber certification organizations that inspect forest operations and issue a label claiming that timber was produced sustainably and in accordance to the FSC’s principles and criteria. The FSC Principles of Forest Management include:

- Compliance with laws and FSC principles.** Forest management systems shall respect all applicable laws of the country in which they occur, and international treaties and agreements to which the country is a signatory, and comply with all FSC principles and criteria.
- Tenure and use rights and responsibilities.** Long-term tenure and use rights to the land and forest resources shall be clearly defined, documented and legally established.
- Indigenous peoples’ rights.** The legal and customary rights of indigenous peoples to own, use and manage their lands, territories and resources shall be recognized and respected.
- Community relations and workers’ rights.** Forest management operations shall maintain or enhance the long-term social and economic well-being of forest workers and local communities.
- Benefits from the forest.** Forest management operations shall encourage the efficient use of the forest’s multiple products and services to ensure economic viability and a wide range of environmental and social benefits.
- Environmental impact.** Forest management shall conserve biodiversity and its associated values, water resources, soils and unique and fragile ecosystems and landscapes and, by so doing, maintain the ecological functions and integrity of the forest.
- Management plan.** A management plan – appropriate to the scale and intensity of the operations – shall be written, implemented, and kept up to date. The long-term objectives of management and the means of achieving them shall be clearly stated.
- Monitoring and assessment.** Monitoring shall be conducted – appropriate to the scale and intensity of forest management – to assess the condition of the forest, yields of forest products, chain of custody and management activities, and their social and environmental impacts.
- Maintenance of natural forests.** Primary forests, well-developed secondary forests, and sites of major environmental, social or cultural significance shall be conserved. Such areas shall not be replaced by tree plantations or other land uses following harvest.
- Plantations.** Plantations shall complement, not replace, natural forests. Plantations should reduce pressures on natural forests (This is a draft principle not yet ratified by FSC membership).

(Source: FSC 1994.)

- **Regeneration:** indicators should reflect natural regeneration rates of important successional and dominant tree species.
- **Biodiversity:** indicators should, at a minimum, reflect the status of key pollinators and seed dispersers. However, since so little is known about the role of most species, it would be better to broadly monitor the status of a cross-section of biodiversity (plants, mammals, birds, invertebrates).
- **Microclimate:** temperature, humidity and soil moisture are crucial determinants of germination and seedling/sapling survival for most tree species and may be affected dramatically by forest-management activities.
- **Nutrients:** indicators should be used that can reflect mineral nutrients, soil organic nutrients, and soil microfaunal levels.
- **Hydrology and erosion:** indicators should measure soil-erosion rates, water quality, and hydrologic regimes.
- **Pathologies, wind, and fire:** outbreaks of insect pests and diseases, windfalls and blow-downs, fuel loading

and fire, and other potential threats to tree species, should be monitored.

Ideally, these indicators would be tracked regularly before, immediately after, and between harvests, and then compared with measurements in control areas. A basic research programme to correlate the impact of management activities with forest ecosystem health indicators will help forest managers balance resource-extraction levels, manage their intensities, and monitor forest health. Social and economic indicators could also be monitored in and around managed areas, since these factors may be more important leading indicators of concern to the maintenance of biodiversity than many biophysical indicators (see Reid *et al.* 1993).

Monitoring such indicators is easier said than done. Since commercial forestry operations are faced with economic constraints that rely heavily on cost-efficient methods of resource assessment, low-cost methods are needed to inventory and monitor production forest areas for impacts on biodiversity.

13.3.4 Managing biodiversity in fisheries

To an even greater degree than with forests, fisheries and the coastal and marine ecosystems that support them are treated as commonly owned resources. Sustainable harvesting of commonly owned aquatic resources has proved difficult, and it has become a truism that declining fisheries have become one of the most notable manifestations of Hardin's (1968) 'tragedy of the commons'. Over-fishing changes the relative species abundance as well as the demographic and genetic structure of populations (e.g. Ryman and Utter 1987; Ryman *et al.* 1994). In region after region, the familiar pattern of increasing catch, population depletion and collapse of a fishery is followed by a switch to exploiting more remote populations and often a switch to less valued species. Of the 176 major fish populations that the United Nations Food and Agriculture Organization (FAO) currently track, 30% are over-exploited. The situation in Europe may be worse where some 90% of North Atlantic fish stocks are being over-fished (Osherenko and Young 1993). With the world population expected to double by 2050 and rising expectations for quality of life, human demands for fish products will increase even as consumption on a per capita basis declines (FAO 1991). The only way to meet these demands is to use more sustainable fishing practices that minimize the risk of irreversibly harming ecosystem structure and essential processes (Beverton 1993).

13.3.4.1 Managing biodiversity in traditional fisheries

Conventional wisdom suggests that commonly owned resources can be sustainably used only if they are converted to private property, or alternatively, if government regulations are imposed. Two key characteristics of

fisheries, difficulty of exclusion and subtractibility (the capability of each user subtracting from the welfare of others), are commonly cited as the reasons for such choices (Berkes *et al.* 1989; Feeney *et al.* 1990). Recent findings in fisheries management (similar to findings in forestry, wildlife, rangeland and water resource management), however, suggest this may be a false choice. Examples from traditional and small-scale fisheries indicate that:

- there is no intrinsic reason why commonly owned resources such as fisheries are doomed to over-exploitation;
- sustainable management is possible under three general kinds of management regimes: private property, state property and communal property;
- examples of successful community-based fisheries and marine resources management are found in many cultures and areas around the world;
- two necessary conditions for successful community-based resource management are the ability to limit the access of outsiders and to make and enforce rules among community members; and
- conservation by self-interested users of a resource may be the most robust approach to sustainability. Incentives for users to conserve must, therefore, be built into any fishery management plan including traditional community-based approaches (McCay and Acheson 1987; Berkes 1989; Ostrom 1990; Bromley 1992).

Many traditional fishermen live in communities in which resource use is never unrestricted and property is never purely private or government-owned. These communities have instead evolved mechanisms of collective decision-making and conflict resolution, and informal regulations to limit non-sustainable practices (Johannes 1978; Ruddle *et al.* 1992). Based on evidence from traditional and artisanal (small-scale) fisheries, a new common property theory has emerged as a basis for more sustainable fisheries management. It emphasizes the role of traditional use rights and traditional knowledge and the importance of property rights and institutions, rather than the earlier emphasis on technical fisheries management and transforming or replacing traditional and small-scale fisheries with large-scale fisheries (Larkin 1988).

In Southeast Asia, traditional marine tenure systems function in various ways. For example, in parts of eastern Indonesia the traditional system of *sasi* or 'prohibition' includes a wide range of customary laws designed to ensure equitable opportunities for deriving both subsistence and economic incomes from coastal resources. These include community-enforced rules regarding the use of gear, times when fishing for particular species is allowed, and size limits. Sanctions for violations include fines, public

shaming, confiscation of fishing gear, corporal punishment, and even exile (Zerner 1994).

On Batanes Island in the northern Philippines, groups of *mataw* fisherman practice sacred rituals to respect their *vanua* or fishing ground, regulate access to the fishing grounds, and set individual daily catch limits (i.e. only nine per fishing trip) for migratory dolphin fish (*Coryphaena hippurus*). In addition, they regulate the fishing of bait species such as flying fish and bait shrimps and crabs to maintain the *mataw* fishing operation. Punishments and fines are prescribed for violations of the 'formal fishing laws' agreed upon for each fishing season (Mangahas 1994). Even where private ownership of fish-aggregating devices (FADs) for nearshore and offshore pelagic fish species such as tuna is recognized (as it is in many Asian fisheries), customary sharing systems may allow outsiders to fish with hooks and lines in the FADs when the owners are not fishing.

In North America, co-operative resource management (or co-management) is used by indigenous peoples in Canada, Alaska and some parts of the mainland United States. In these areas, indigenous communities share authority and responsibilities with federal and state agencies (Berkes *et al.* 1989). These co-operative management regimes are designed to maintain and re-invigorate indigenous systems of territoriality and social control that contribute to sustainable and equitable resource use (Young *et al.* in press). Native rights are recognized by a variety of treaties, acts, laws and regulations, which differ from place to place. Social scientists studying co-management regimes find that they typically include socially defined groups, territorial limits, patterns of use that are both socially reproducible and multi-dimensional, and collaborative mechanisms for effective and appropriate monitoring and regulation (Young *et al.* in press).

Three types of factors contribute to sustainable fisheries and marine resources management (including marine mammals) by traditional cultures in North America:

Unintentional factors. Limited financial resources restrict access to distant areas and limit the type of gear that can be used. This keeps catches lower than they might otherwise be and ensures that some waters are fished infrequently or not at all. As a result, refuge stocks and genetic diversity are maintained. Government policies and social changes have also concentrated populations in villages where schools, medical and support services are available, thus enhancing this effect.

Cultural factors. The concept of fishing for personal wealth or to enhance status in the community has been uncommon in many cultures: fishing was limited to catching only what was needed by the fisher, his family and others in the community. Seasonal patterns of

harvest evolved over time to maximize returns with minimum effort – for example taking salmon during spawning runs – in ways that may have the least impact on population structures. Taking only certain-sized fish may contribute to maintaining fish community structure (Berkes 1977; Hopper and Power 1991). Cultural factors, however, may become less important in the face of increasing costs associated with fishing.

Outside controls. Laws and regulations for conservation by state/provincial and federal authorities are often – though not always – accepted to help maintain fisheries and marine resources in the face of pollution, introduced species, and multiple outside demands on resources. These are imposed by non-indigenous organizations, often in the name of conservation (Collection Nordicana 1992).

The future of traditional fisheries and marine management is, however, uncertain in many parts of the world. Pollution in the Russian Arctic and elsewhere may pose significant risk to indigenous use of marine mammals. Political debates arising from uncertainty about the status of marine mammal populations reveal differences between indigenous and Western scientific knowledge systems (Bielawski 1992). In the International Whaling Commission deliberations about Alaskan bowhead whale stocks, indigenous knowledge and management systems have often been overlooked or dismissed by scientists (Huntington 1992). Changing ecological dynamics, introduction of new technologies, uncertainty about the status of marine mammal populations, the impacts of outside resource users and managers, and conflicts over hunting marine mammals, have dramatically altered Aleut relationships with sea otters and seals (Veltre and Veltre 1987). Ideological battles are waged over the appropriateness of killing marine mammals (Lyng 1991).

In tropical nearshore waters in Asia and Oceania, most traditional marine tenure and management systems are not well documented (Johannes *et al.* 1991), despite a resurgence in awareness and appreciation of such systems (Hatcher *et al.* 1990). Nevertheless, many fishery managers continue to assume that fishermen will over-harvest the resource if left to their own devices. While such assumptions are not universally justified, community-based management in many areas is breaking down in the face of population growth, social and political disintegration, technology change, commercialization and habitat degradation and pollution (Berkes 1989; Ostrom 1990).

Traditional rights have become more ambiguous under these conditions and, in part because they are not clearly defined in government statutes, are the source of increasing disagreement over their interpretation (Pearse 1988). In North America the recent tendency has been to recognize

the special rights of native groups to fish for food but not necessarily to fish for trade or commerce. New agreements, land-claim settlements and regulations give precedence first to conservation, then to native food fisheries, before other uses can be entertained. The balance of rights between various users is unstable, nevertheless, and commercial and sport fisheries interests frequently engage in conflicts over traditional rights (Cooley 1963; Larkin 1979; Mullan *et al.* 1992).

Traditional practices and customs, however, are finding new life in revised legal frameworks and management systems for coastal management in some areas. For example, in the Moluccan islands of Indonesia the traditional *sasi* system is being reinterpreted by some government leaders and NGOs to help develop new approaches to coastal and marine management. Such approaches, if they are to be effective, will need extensive education efforts, administrative and legal reforms, resolution of potential tenurial conflicts over community-based marine management areas, and experimentation through the establishment of carefully designed and monitored pilot projects (Zerner 1994). Projects in the Philippines and South Pacific that integrate the idea of a totally restricted marine reserve with a marine conservation area under sustainable local controls (White 1989; Johannes *et al.* 1991) recognized by national and local government may hold wider promise for the sustainable use and management of marine biodiversity – at least in areas where traditional systems are still partially intact.

13.3.4.2 Managing biodiversity in small-scale fisheries

In most countries, small-scale fisheries are common. These fisheries use smaller boats and gear than large-scale deep-sea fisheries, but are not bound by the norms of traditional fisheries. The major problems of small-scale coastal fisheries are overfishing and the degradation of habitats such as coral reefs, seagrass beds, mangrove forests and estuaries (e.g. Pauly and Chua 1988). Several measures are used to address these problems. National fishery agencies normally regulate specific fishery resources through imposition of closed seasons, minimum sizes of organisms caught, regulation of mesh size, limitation on gear types, etc. However, because of the weak enforcement capabilities of many such agencies, there is often little compliance with these measures (Pauly *et al.* 1989).

Management interventions to abate further deterioration and rehabilitate degraded marine habitats include, for example, seagrass and mangrove replanting (Gan Boon 1993) and the setting up of artificial reefs. Unfortunately in many cases, setting up of artificial reefs has functioned more as a fish-attracting device, contributing further to overfishing rather than acting as a means of conserving and managing reef fisheries (e.g. de los Angeles and Pelayo 1993).

Many tropical countries have increased the establishment of multiple-use marine parks (Salm 1983; Kelleher and Kenchington 1984; McManus 1988; see also 13.4.1) in line with integrated coastal management programmes. There is little or no active management in many of these areas, however, and few of these conservation areas have been assessed for their effectiveness (Alcala 1988; Hatcher *et al.* 1990).

Water pollution has also contributed to the decline of fishery resources. While strict pollution-control policies have been adopted by national governments and co-ordinated through regional programmes, their success has been limited (reviewed in Portman *et al.* 1989; Brodie *et al.* 1990; Gómez *et al.* 1990; Sen Gupta *et al.* 1990).

In developing tropical countries, the failure of many conventional fisheries measures is ultimately caused by acute socioeconomic pressures (Pauly *et al.* 1989), pressures not easily addressed by better enforcement or narrowly focused policies. In a broad sense, fisheries management in Southeast Asia, for example, is challenged more by social and economic conditions ('people problems') than by a lack of suitable resource management tools. This is illustrated in the Philippines, where 3.5 million artisanal fishermen share about 50% of the country's fishery production (Smith 1979). Consequently, management of inshore tropical waters must include efforts to alleviate fishing pressure by developing alternative sources of livelihood for artisanal fishermen. This may include livelihoods that have no direct connection to the fisheries resource such as tourism, small business enterprises and household cottage industries, or it might mean developing aquaculture for food production (see 13.3.4.5). Aquaculture is also being used to restock depleted natural fisheries (see 13.3.4.5). Finally, public education is a critical component in the implementation of sustainable use and management measures (e.g. White 1989).

Community-based fishing co-operatives are increasingly advocated as a means of improving the livelihoods of small-scale fishermen and of strengthening local resource management, especially in the Caribbean and some Asian nations (Renard 1991; Poltan-de la Cruz 1993). In some areas, including the Turkish coastal fisheries (Berkes 1986), Maine lobster fisheries (Acheson 1975), and Japanese coastal fisheries, laws place the control of the local resource in the hands of community-based fishing co-operatives (Ruddle 1987). These initiatives are departures from prevalent forms of more centralized *de jure* state control of fisheries resources and *de facto* open access conditions on the water. Decentralization of resource management through the granting of some territorial use rights (Garcia 1992), some of them closely akin to traditional marine tenure systems, may actually strengthen the sustainable use of fisheries.

For example, in the Philippines, the 1991 Local Government Code confers jurisdiction over marine areas within 15 kilometres of the shoreline to local governments and provides preferential rights for organized artisanal fishermen – in effect recognizing the limited ability of national and provincial governments to manage the resource effectively. This devolution of legal control has set in motion widespread community organizing, participatory applied research, and community-based management planning. It has also stimulated greater interest in, and use of, traditional knowledge and traditional marine tenure systems as part of contemporary management practices.

The common property framework suggests that property rights regimes may be combined in order to effectively address a particular resource management problem. Fishery regulations in parts of Europe, for example, are jointly developed and negotiated between governmental managers and local fishermen. In the Lofoten Islands cod fishery in Norway, the state empowers fishermen to update regulations and enforce them under the Lofoten Act of 1890 (Jentoft 1985).

Because of the widespread limits of governments to define, monitor and enforce suitable regimes to use and manage fisheries sustainably, the sharing of management power and responsibility between the state and the fishing community (co-operative management or co-management) is receiving increased attention around the world (Pinkerton 1989; Pomeroy 1993). The co-management model is particularly useful if management of the fishery is complicated by a diversity of users. To retain incentive structures for community-based conservation, such management approaches generally seek to include as little government regulation as necessary and as much local-level control as possible.

13.3.4.3 Managing biodiversity in large-scale fisheries

What are the obstacles to sustainable harvesting in large-scale fisheries? Scientific knowledge is often sufficient to indicate unambiguously the direction in which management should go – at least for major long-established fisheries. While information on living aquatic resources is limited for offshore fisheries in many developing (and some developed) countries, the most important obstacle is the lack of control over access to fisheries and fishing effort. The failure of politicians to address these factors has greatly limited management effectiveness. Fisheries managers and the fishing industry itself are only reluctantly coming to accept that technical measures alone (e.g. minimum mesh sizes of fishing gear) will rarely be sufficient to maintain or rebuild fisheries stocks. In some cases, they are also questioning the effectiveness of catch quotas where rigorous monitoring and enforcement are not in place.

In theory, fish populations can be harvested sustainably in large-scale fisheries with proper management. Even long-lived species (such as tuna or whales) have a high intrinsic rate of increase that should allow the harvest of surplus production (May 1976). In the 1950s, a substantial effort was mounted to develop quantitative theories of fisheries management that could be used to avoid stock depletion. For example, the development of surplus-yield models (Ricker 1954), which provided the foundation for cohort analysis, and dynamic pool models (Beverton and Holt 1957) were used to provide estimates of the maximum equilibrium catch or maximum sustainable yield (MSY). However, the surplus-yield models ignored population structure and contributed to the over-exploitation of some fisheries (Larkin 1977; Hilborn and Walters 1992). They are now held in some disrepute.

Modern dynamic pool models are a further development of Beverton and Holt's (1957) early models. These models include four main sub-models:

1. individual growth rate;
2. recruitment rate of the population;
3. natural mortality rate; and
4. fishing mortality rate.

Each sub-model can be broken down into complex and realistic systems that include demography, the effects of environmental variability, and interactions between the target population and predators, competitors and prey species. The goal of scientific management of large fisheries is to quantify the variables in the four sub-models, and based on this, estimate yield. This is, however, a difficult task. Even simple multi-species models are still not effective management tools in most systems, given current knowledge (Kock 1992).

Although the exact maximum sustainable yield is difficult to know before populations become overfished (Hilborn and Walters 1992), MSY has been a useful concept for discussing fishery management problems (Gulland 1989). It serves three distinct functions by providing a description of the status of fish stocks in relation to exploitation, a quantitative management objective that can be monitored, and a measure of the success of population management. Maximum sustained yield values, however, must be evaluated continuously to allow for the variation in population abundance that occurs in all natural systems because of demographic and environmental variability. Otherwise, population sizes may fall below ranges upon which the initial MSY values were based. When the demographic parameters of a harvested population are unknown and uncertainty in the estimates of the total population is high, the optimal strategy is to avoid large short-term harvests and set management objectives below MSY values that have been determined by incomplete or uncertain data.

Accurate yield estimates based on multispecies models are in most cases a future goal, not a current reality. Simpler methods are therefore needed to estimate MSY. According to Beverton (1993), optimal catch most often appears to be achieved when the spawning stock biomass is one-quarter to one-third that of the unfished size of the fish population. However, the unfished biomass is unknown in most heavily fished populations and, in any event, it is highly variable. A simple and more robust guide to MSY is a fishing rate of between one-and-a-half to twice the natural mortality rate. In sharks and rays (elasmobranchs), which are long-lived and have low fecundity, MSY is likely to be reached when fishing mortality is much closer to natural mortality rates (Beverton 1993).

If all stocks were fished close to their real MSY, most of the problems of overfishing and conservation would be resolved. However, it is possible to do even better than trying to fish at MSY. Because the response curve of yield is relatively flat in the region of MSY, it means that 95% of the expected MSY could be achieved with 30% less fishing and hence a 20% higher spawning stock biomass. This small sacrifice in expected yield makes good sense economically because it results in higher catch-per-unit effort, larger average size of fish caught, and reduced variability in catches. The larger stock would also provide a better cushion against inevitable regional and potential global climate changes.

In most stocks the reduction in population caused by harvesting at MSY would be less – often a great deal less – than the natural demographic variability that species are adapted to. Some modification of this simple principle is needed for fisheries with multispecies communities that have strong biological interactions, such as the cod, capelin and herring fisheries in the Barents Sea (Beverton 1993; Hamre 1994; Gjøsæter 1995). In such cases, adaptive management informed by good science is essential for achieving a balanced harvest of the interacting species (Hilborn and Walters 1992).

13.3.4.4 Newly evolving practices in large-scale fisheries

Concern over the sustainable use of aquatic resources is not new. Since the turn of this century, numerous international conferences have been convened and several international fisheries management bodies have been established to address the need to develop fisheries management regimes that maintain stocks and protect other aquatic species (e.g. seabirds, marine mammals, sea turtles, etc.) from the effects of fisheries exploitation. Recently, FAO's Committee of Fisheries (COFI) developed the concept of 'responsible fishing' to encompass a broad range of principles for the sustainable management of marine resources, including biodiversity. These principles are intended to ensure the sustained yield of diverse fish stocks from oceanic, coastal and inland fisheries, and to ensure the maintenance of biodiversity.

Responsible fishing is based on a management regime with the following characteristics:

Development of more reliable scientific information.

Although there have been significant achievements in fish stock assessments, there is room for substantial improvement in data collection, statistical analysis, and the understanding of ecosystem interactions on the development of single stocks.

Better use of scientific information in management.

Total allowable catches (TAC) for fish stocks are set by the fisheries management agencies, often at levels higher than those recommended by resource biologists. There are many cases where this (mal)practice has resulted in overfishing and stock depletion.

Development of selective fish-capture methods.

Globally, 80 million metric tons of marine 'target species' are landed on an annual basis. However, recent estimates indicate that an additional 30 million tonnes of non-target fish (by-catch) are discarded annually – an amount equal to 25% of the target catch – because the species or size is non-marketable. Recent work has focused on the problem of by-mortality of fish and other organisms that are not actually caught but may suffer mortality after escapement from fishing gear. This mortality should be included in stock assessments and steps taken to reduce by-catch and by-mortality.

Combining fisheries regulations with better control measures.

Most major fisheries are now regulated by various means (quotas, minimum mesh size of gear, minimum legal fish size, time and area restrictions of fisheries, etc.). Together, the various regulations represent an important element of the responsible fishing concept. However, the success of these regulations is highly dependent on good control measures. The introduction of exclusive economic zones (EEZs) of 200 nautical miles has greatly improved the enforcement of fishery regulations, as the stocks within the EEZs are under jurisdiction of the respective coastal states.

Imposition of management and control on the high-seas fisheries.

Fisheries on the high seas – or parts of the oceans not covered by national EEZs – are not managed or controlled. This is particularly a problem for straddling stocks and highly migratory species that are distributed, at least partially, outside national EEZs and thus accessible for uncontrolled exploitation. This part-time access of the commons to otherwise nationally controlled fish populations is a major loophole in the proper management of these stocks. There is an urgent need for

the international community to find solutions to the jurisdiction and management of the high-seas fisheries.

These elements of responsible fishing are likely to be a cornerstone of future marine fisheries use. In addition, responsible fishing must include efforts to manage harvest levels and methods so that commercial fishing does not endanger other marine species. The use of turtle exclusion devices (TEDs) in the Gulf of Mexico shrimp fisheries, the banning of drift-net fishing in the Pacific, and a number of other efforts are steps in this direction. Other steps will need to include defining minimum biologically acceptable levels (MBALs) for populations of seabirds, marine mammals, and other non-target species, and then monitor the impact of fisheries harvests on these levels and adjust quotas and other management goals accordingly. New international mechanisms or existing global agreements, such as the Convention on Biological Diversity, should be used to obtain a general agreement on how marine biodiversity (i.e. non-commercial species) can be maintained under commercial fishery management regimes.

13.3.4.5 Managing biodiversity in aquaculture

Aquaculture is the farming of fish and other aquatic organisms (e.g. crustacea, molluscs, macro-algae) for food and other purposes. While only about 13% of the world's fish and other aquatic produce comes from aquaculture, it is growing rapidly; at 6–7% annually, it is currently the fastest-growing food production sector in the world (Pullin 1994). Despite this growth, aquaculture is relatively undeveloped compared to agriculture and capture fisheries from coastal, marine and inland waters. With global declines in capture fisheries, and limited growth in agricultural production, aquaculture will continue to expand rapidly in coming decades.

To sustain that expansion, the genetic diversity of farmed organisms must be managed sustainably. Aquaculture productivity also depends on a wide diversity of other aquatic organisms for food and for maintenance of water quality. Aquaculture, in turn, can have adverse impacts on the diversity of natural populations of aquatic organisms and the structure of ecosystems through the release of farmed organisms or, for example, the conversion of mangrove forest habitats to shrimp ponds.

Most aquaculture produce comes from about 200 species. For example, Pullin (1992) estimates that 95% of aquaculture production comes from 181 species – six seaweeds, 43 molluscs, 27 crustaceans and 105 finfish. Intraspecific genetic diversity, which is relatively well known in agriculture, is virtually unknown except for common carp (*Cyprinus carpio*), some salmonids and catfish, and more recently tilapias (Eknath *et al.* 1993).

Since domestication for most aquaculture organisms has not progressed far, most farmed organisms are close to wild

types (Pullin 1994). Genetic diversity, therefore, is a barely tapped resource for domestication and productivity improvements. A growing array of technologies, including gene transfer, is being used by fish breeders even before more conventional breeding methods (selective breeding and hybridization) have been applied to most species.

Aquatic biodiversity is being lost at alarming rates in natural systems, especially inland waters. For example, Moyle and Leidy (1992) estimate that at least 20% of freshwater species are already extinct or in serious decline. The vast majority of this decline has been caused by pollution, human-induced structural changes in aquatic habitats, and the release of introduced species. These losses will constrain efforts to evaluate the aquaculture potential of aquatic organisms. Indeed, it is now becoming difficult for fish breeders to locate and collect genetic materials from healthy or relatively undisturbed wild populations (Pullin 1988, 1994).

Documentation of wild genetic resources and threats to their survival is the first step toward implementing specific measures to protect the wild populations and their environments. The International Center for Living Aquatic Resources Management (ICLARM) and FAO have developed a database (FishBase) that now includes nearly half the world's finfish, including nearly all of those that are directly useful to humans. The database includes information on the degree and type of threats to fish species in addition to an array of taxonomic, genetic, physiological and ecological information on each species (Froese and Pauly 1994). Distributed on CD-ROM, this database is now being used by international, national and state/provincial management agencies in Europe, Africa, Asia, Latin America and the United States. Pullin (1994) suggests identifying opportunities to protect and sustainably manage endangered aquatic species, such as those found on FishBase, within larger programmes for protected areas and terrestrial wildlife species management.

Like agriculture and forestry, aquaculture can have serious adverse impacts on biodiversity, possibly even more so because of the connected fluid environment of aquatic ecosystems. The escape of captive-bred fish, for example, can contribute to the loss or depletion of wild stocks through predation, competition for food and breeding sites, the spread of disease, changes in water clarity or turbidity, and interbreeding with wild stocks (Billington and Herbert 1991). Risks of adverse environmental impacts are generally higher with exotic species than with indigenous species. In many countries, especially developing countries, there is virtually no active effort to prevent introductions, and quarantine measures for transferring stock are generally lacking.

The potential impacts of aquaculture on biodiversity have sparked fierce debates over the need for stricter measures to prevent intentional and accidental release of captive organisms. Legacies of escapes are widespread and often appear to be permanent. For example, the golden

snail (*Pomacea*) escaped from captivity in the Philippines and now infests over 400 000 hectares (Acosta and Pullin 1991). Such escapes can also affect aquaculture directly. Feral populations of a tilapia species initially favoured for aquaculture (*Oreochromis mossambicus*) have spread throughout the tropics and subtropics and are now hybridizing with one of the tilapia species (*O. niloticus*) currently preferred in aquaculture (Macaranas *et al.* 1986). The effects of hatchery programmes on wild stocks is vigorously debated, with some (e.g. Hilborn 1992) arguing that hatchery programmes are contributing to a serious loss of genetic diversity in wild populations, while others (e.g. Nehlsen *et al.* 1991) argue that many other factors could be responsible for genetic decline.

Broad overviews, such as that provided by Hindar *et al.* (1991) suggest that escapees from aquaculture pose a significant threat to genetic diversity in wild (and sometimes captive) populations of fish. The following measures, drawn from a number of sources (Billingsley 1981; Ryman 1981; Allendorf 1991; Hindar *et al.* 1991; Waples 1991; Hindar 1992; Hansen and Jonsson 1994), are recommended to maintain diverse stocks to improve aquaculture and minimize the adverse impacts of aquaculture on wild stocks:

Closed culture: better containment to prevent escape of the organism.

Sterilization: easily induced way of avoiding direct genetic effects.

Localization: locating farms away from wild populations, and choosing locations for sea ranching that minimize straying so as to reduce gene flow to wild populations.

Coastal parks: providing totally protected areas for valuable wild populations.

Reduced or selective fishing: protecting native populations by reducing fishing pressure or by directing that pressure toward cultured fish.

Restrictions on transport: reducing the spread of exotic genes and diseases by restricting transport of live fish and eggs.

Gene banks: counteracting extinction of local populations by the establishment of gene banks.

Minimal genetic differences from native populations: reducing effects of gene flow by minimizing the genetic differences between escaping or released fish and recipient wild populations.

Training of workers: basic training of aqua-culture workers (including non-specialists) to minimize the risk of accidental releases of organisms into aquatic ecosystems.

medicines, dyes, fibres, tools, religious purposes and cash income. Such harvests are motivated by cultural traditions, by survival needs, for cash income, and for recreation. Although there is no comprehensive source of data to document the full extent of trade in wild species products, Fitzgerald (1989) using CITES statistics estimated that the international trade in primates, ivory, orchids, reptile skins, furbearers and tropical fish was worth US\$5 billion in 1986. Moreover, hunting, sport fishing, and other uses of wild populations (e.g. mushroom collection) are at the centre of rapid growth in recreation and tourism in both developed and developing countries. For example, the US Fish and Wildlife Service estimates that wildlife-related recreation (e.g. hunting, fishing, birdwatching) in the states of Oregon and Washington contributes as much as US\$2 billion in direct and indirect benefits annually to the regional economy (USFWS 1988). See Section 12 for further discussion on the valuation of wild species.

While substantial research efforts and money are invested in many countries to manage game populations and sport fisheries, efforts are only now beginning to assess the impacts on biodiversity of many human uses of wild species. Again, as with sustainable forestry, agriculture and fisheries management, one of the keys to the successful management of wild species is restricting access to the harvest of wild populations.

13.3.5.1 Wildlife management

Harvesting wild plants and animals influences the composition, structure and functions of populations and ecological communities. Diversity and density may decrease due to selective harvesting of sex, age, size or other phenotypic types. Deer hunting, for example, is often targeted at large, dominant males. Before European settlement in North America, wapiti (*Cervus elaphus*) were opportunistically harvested without respect to sex and age. Since European settlement, harvesting has become more selective and targets older males. As a consequence of the new harvesting regime, the population structure has changed and individuals have experienced a decrease in longevity (Davis 1983).

Harvesting, however, can also maintain the vitality and productivity of a population, especially in the absence of natural predators. On St Matthew Island, Alaska, the introduction of reindeer, their rapid population growth and subsequent population crash indicates how a lack of management, including harvesting, can lead to problems (Klein 1968). Productivity is often maximized at an intermediate population density. Harvesting regimes, informed by data on demographic and population trends, may serve to maintain viable populations and healthy individuals as illustrated in Scandinavian cervid herds (see Box 13.3-5).

13.3.5 Managing wild flora and fauna

Wild animals and plants are harvested by people throughout the world for food, shelter, traditional

Early wildlife management models were based on the ecology of the individual species of interest. Management approaches now often recognize differences in the individual populations that are harvested (Caughley 1994). This, however, requires precise ecological information, which is frequently unavailable (Gross *et al.* 1992). In some cases, too, rare individuals of a certain phenotype or genetic composition may have effects on the population far beyond their relative biomass and numbers. Environmental variation causes much of the change in the size of a population and promotes the coexistence of genotypes or species in communities. Recent theoretical and empirical results have identified conditions that relate environmental variation to long-term population dynamics (Lubchenco *et al.* 1991). These findings are directing attention to the ways in which environmental fluctuations affect populations.

In addition to environmental change, harvested populations can rise and fall in relationship to other species and there is a need in wildlife management to develop multi-species models which should at least include the

harvested species and their resource base. Ideally, they should include *all* important associations related to the sustainable harvesting of the species of interest. Furthermore, wildlife management models should account for stochastic environmental factors such as weather conditions, which may affect the resource base for the target species.

Future management models should also include risk assessment for extinction in the context of changing environmental conditions (Lande *et al.* 1994). In cases where population estimates are uncertain, and detailed demographic data do not exist, the optimal long-term strategy is to harvest at less than maximum sustained yield (MSY) (see 13.3.4.3). Harvesting at the calculated MSY level should occur only when adaptive management techniques indicate what that level is.

13.3.5.2 *International commerce in wild species*

The export value of wildlife products is large. Based on the Fitzgerald (1989) estimate of international trade in exotic

Box 13.3-5: Management of cervid populations in Norway.

Since prehistoric times in Norway, cervids (moose, red deer and reindeer) have represented an important food resource for people, and have provided raw material for clothing and tools (Gjessing 1945; Ahlen 1965). Early settlements were often associated with extensive trap systems for cervids (drift fences, bow stands and pitfalls) operated and maintained through co-operative efforts (Gjessing 1945; Molmen 1988). The predictable occurrence of different species in space and time, and the potential catching capacity of the trap systems, influenced both the location and organization of the communities (Skogland and Molmen 1979; Langvatn 1990; Andersen 1991).

Today, the harvest of moose, red deer, reindeer and roe deer in Norway is regulated through permits issued by municipal wildlife boards, usually specifying sex and age categories of animals that can be shot each year. The number and specification of hunting permits issued are based on censuses, information on population structure, and habitat area.

Monitoring the demography, physical and reproductive performance, and habitat status of different cervid populations is a vital part of long-term sustainable management. A sub-sample of 10–20% of the animals harvested each year provides an accurate analysis of age distribution, cohort variation and reproduction (Skogland 1985, 1988; Langvatn and Albon 1986; Langvatn 1993; Albon *et al.* 1992; Andersen and Heim 1993; Saether and Heim 1993; Langvatn *et al.* 1995). Cervid populations exert a significant effect on vegetation, and may affect habitat structure and species composition in an area. Ongoing monitoring of the impact of cervid populations on their habitats is also an important part of a harvesting policy that focuses on the vitality and viability of cervid populations and concern for maintaining biodiversity in general.

Harvests of cervid populations entail potential threats to demographic as well as genetic diversity of the populations. The issuing of permits aims to avoid drastic fluctuations in population size, thus preventing genetic drift at low levels, and habitat deterioration and reduced performance of the individuals at high population densities. It attempts to harvest different sex and age categories approximately in proportion to their occurrence in the population (Gill 1990).

In recent decades moose, red deer and roe deer have expanded their geographic ranges and increased to their highest population levels in historical times. Expansion of natural and planted forests may be one factor that has enhanced environmental conditions for cervids, except for the reindeer which depend on open grassy tundra and meadows. Improved harvest patterns have also contributed to a more robust and productive demography in present cervid populations.

wildlife products, and considering the substantial but largely undocumented trade in non-timber forest products (e.g. rattan, fruits, dyes, mushrooms, crafts, etc.) and wild medicinal plants, Edwards (1995) believes the international trade in wild species rivals that of the forest and fisheries sectors.

The trade of wild fauna and flora is restricted under the Convention on International Trade in Endangered Species of Wild Flora and Fauna (CITES) to which 122 countries (as of July 1994) are Parties (see also 13.6). Species considered to be endangered are prohibited from trade and are listed in Appendix I of the Convention. Appendix II lists species (and products derived from them) that are allowed in international trade under specific guidelines and subject to monitoring and reporting in an effort to minimize the impact of legal trade on species survival. Approximately 675 species are listed in Appendix I, and Appendix II includes about 3700 species of animals and 21 000 species of plants, a figure that is imprecise because entire families, such as orchids, and genera are listed.

Trade in species listed in Appendix II is regulated through the issue of export permits, when there is a determination that the harvest of the species or product has not been detrimental to the survival of the species in the wild. In most cases, however, exporting countries do not have the capacity to make such a finding. Rather than make a determination for each permit, many countries have resorted to using an export quota for the species (often based on previous years' export records) as a basis for controlling harvests.

Virtually all countries participate in the trade of Appendix II listed species. Most of the reported exports come from a handful of countries in Asia (e.g. Indonesia, Philippines, Thailand), South America (e.g. Argentina, Bolivia and Guyana) and Africa (e.g. Cameroon, Tanzania and Mali) (WRI 1992). Historically, the principal markets for wild flora and fauna were in the United States and European countries. However, the majority of the trade is now directed at several Asian countries (e.g. Japan, Singapore, Hong Kong, China and Taiwan), while the United States and a few European countries (e.g. Germany, Belgium, France, Austria, Italy and the United Kingdom) import most of the rest.

As commerce in wild species has become more regulated and controlled, captive management or cultivation of species has begun to replace supplies traditionally harvested from the wild. Butterfly ranching in Papua New Guinea is a successful example where ranching has produced economic benefits and protected the wild resource. In this case larvae are collected from the wild, food plants are cultivated by rural villagers, and the 'captive stock' are cared for and harvested just prior to metamorphosis. The Government of Papua New Guinea assists communities in marketing their products, and the

income goes to the villagers. Other examples of successful ranching include green iguana lizards in Central and South America (Ocana *et al.* 1988) and crocodiles in Papua New Guinea, although a lack of market development has limited their potential (Edwards 1995).

13.3.5.3 Incentives for managing wild populations sustainably

In most countries wild resources are the property of the state and access is subject to state regulations. In developing countries, the people living closest to wild resources will have the greatest influence over their conservation. Where people are poor, or where enforcement is absent, wild species will often be harvested irrespective of legal regulations. Given these realities, two conditions must be addressed in national policies:

1. the people living with the resources should have sufficient incentives to conserve, and
2. resource users must be accountable for their actions.

Rights to harvest wild species can be conveyed through property ownership. In this situation, the owner of the land has the legal right to use all resources on the land including wildlife and plants. Alternatively, usufruct (limited) rights to wild resources can be granted by government on public lands. In either case, the rights should convey responsibilities in relation to a defined management plan and should include periodic reviews of performance to ensure accountability.

In cases where landholders have the responsibility for managing of wild resources (either on privately owned land or on communal lands), there is some evidence that this has improved the status of the wild resource more than has public management. For example, the government in Zimbabwe has actively promoted a policy of 'private ownership' of wildlife. As a result, 75% of ranches in Zimbabwe derive some income from wildlife, and overall the amount of private land dedicated to wildlife management has been increasing at 6% per year, according to a recent survey (Martin 1994). Today, national parks account for less than 30% of the country's managed wildlife estate while privately owned and communal lands account for nearly 50% (Cumming 1991).

To compete with other forms of land use, the value of wild species harvests must be factored into land-use planning decisions. Policies in some areas are contributing to the conversion of natural habitats that may be more valuable for wildlife or wild plant harvesting. In Zimbabwe, research indicates that lands managed for wildlife will generate up to 30 times more income from sport hunting, wildlife viewing, and meat, hides and other products, than the same land would generate if used for cattle ranching (Bond 1993).

Recent research from Kenya, however, suggests that the opportunity costs may exceed the benefits of some of the

country's best-known wildlife reserves and protected areas (Norton-Griffiths and Southey 1995), although Kenya has not diversified its wildlife sector in ways – sport hunting is banned, for example – that could enhance revenues (Edwards and Allen 1992). This illustrates one of the major difficulties in the management of wild resources: the price of a single species product in most cases cannot reflect habitat management costs. However, amortizing these costs across an array of species and products, over a number of years, may make the investment economically feasible. Multiple uses of wild species or habitats add value to the resource. Likewise, given the vicissitudes of market demands for wild products, it is not advisable (nor probably sustainable) for a management programme to be based on a single species. In Zimbabwe, for example, an elephant may be harvested for meat, used to make a variety of wildlife products, marketed for sport hunting, and promoted for tourism. Successful crocodile farming operations in various countries have incorporated tourism and sale of breeding stock into their business activities. Each additional use adds to the potential value of the resource and increases the incentive to maintain and manage the resource.

The value of wild habitats and their species to rural communities is often overlooked in national policy. Rural people can be (and often already are) allies – not adversaries – in the sustainable management of wild resources. Government agencies and NGOs will need to invest heavily in working with local communities to educate and train residents to be wildlife managers and to use wildlife to meet their social and economic development goals. In the few places where this has been done, such as Zimbabwe's Campfire Programme (Child 1994), wildlife and biodiversity have not only held their own but actually increased.

13.3.6 Biodiversity prospecting

The search for wild species whose genes can yield better crops and new medicines – sometimes called 'biodiversity prospecting' – has created a rapidly growing new industry. Already, pharmaceutical companies are screening the genetic storehouses found in Costa Rica, Brazil, Micronesia, China and other biologically diverse countries, as well as forest habitats in temperate countries and hydrothermal vents deep under the sea. Without appropriate legislation, benefit-sharing arrangements and technical guidelines, this 'gene rush' may do little to conserve ecosystems and provide few if any benefits to the people living in or near them. Done well, though, bioprospecting can bolster both economic and conservation goals while advancing medical and agricultural needs to sustain growing human populations (Lash 1993).

For decades, ecologists and environmentalists have argued that agricultural, pharmaceutical and other commercial applications of biodiversity should help justify

its conservation. Since the mid-1960s, however, industry investment in natural products research had been small, even declining during the 1970s (Reid *et al.* 1993). As noted above in Section 11, in September 1991, Costa Rica's National Biodiversity Institute (INBio) – a private, non-profit organization – and the US-based pharmaceutical firm Merck & Co., Ltd. announced an agreement that helped reverse this trend. The agreement provides US\$1.135 million to INBio from Merck to conduct research and sampling of wild plants, insects and microorganisms in exchange for chemical extracts which Merck could screen for potential pharmaceutical applications. If any commercial products resulted, Merck agreed to pay INBio royalties which INBio will use to further its inventory and research, and to support a fund for the management of Costa Rica's national parks (Reid *et al.* 1993). Since then, a growing number of biodiversity prospecting agreements have been negotiated between industry, research institutions and governments around the world.

The dramatic changes taking place in the use of biodiversity in the agricultural and pharmaceutical industries are primarily the result of advances in gene transfer and biochemical screening technologies. Breeders can now move genes from unrelated species into agricultural crops through genetic engineering. For example, breeders are now screening plant extracts for antifungal or antiviral activity, isolating and transferring the genes responsible for those chemicals into elite crop lines within a matter of days (Reid *et al.* 1995). In the pharmaceutical industry, natural products drug discovery processes have traditionally required substantial quantities of material. Advances in techniques for extraction, screening, fractionation and chemical identification now require much less material and are much less costly. Samples of only 200–500 g of dry plant material are now needed to isolate, elucidate the structure of, and test a novel plant metabolite, instead of the 100 kg or more that may have been needed a decade ago. Where the screening of 10 000 samples would have cost US\$6 million in the mid-1980s, it now costs only US\$150 000 (Reid *et al.* 1995). And, tissue and cell culture – the 'next frontier' of natural products research – now allows small samples of plants to be collected and screened without any need to return for additional supplies (see Section 10 for discussion of biotechnologies).

The potential of biodiversity prospecting to adversely impact genes, species and ecosystems is much less than that of many practices in agriculture, forestry and fisheries. Unregulated biodiversity prospecting, however, can speed the destruction of a species. In one particularly notable case, the entire adult population of the shrub *Maytenus buchananii* – the source of the anti-cancer compound maytansine – was harvested (27 215 kg) in Kenya by the US National Cancer Institute for testing in its drug

development programme (Oldfield 1984). To avoid such problems, research agreements, such as those specified under the Philippines Presidential Executive Order on Biodiversity Prospecting (Reid *et al.* 1995), can specify ecological and population studies to determine limits for sample collections. All collections must be approved in accordance with these limits.

The greater challenges are to implement mechanisms to equitably share the benefits of biodiversity prospecting and to invest some of those benefits in biodiversity conservation. This is complicated by the new ways in which biotechnology generates wealth and the lack of legal and institutional experience to ensure that benefits are equitably shared.

The economic value of wild biological diversity is increasing because of biotechnologies. Any organism is now a source of chemical and genetic innovation with potential application in the agriculture, pharmaceutical or industrial chemical industries. And, the cost of working with new genetic material or identifying and isolating new chemicals is decreasing rapidly. Ironically, while the economic value of genetic resources in general is rising, the same is not true for the commercial value of any given species or extract. This is because the technological advances that make biodiversity prospecting feasible have greatly increased the effective supply of species. Plant breeders no longer have to restrict their search for new genes to crop relatives, or even to the plant kingdom. In the near term, there is competition among firms for access to a relatively small number of quality suppliers of raw biochemical and genetic material. Over the long term, the large supply of material and decreasing costs of natural product research are likely to hold the 'market' value of samples of raw materials very close to the direct labour cost of obtaining the sample (Reid *et al.* 1995). In other words, most of the benefits from biodiversity prospecting will not come from finding raw materials: they will come from developing those materials into commercial applications.

The keys to sharing the benefits that flow from biodiversity prospecting will depend on two issues. First, how can mechanisms be designed and implemented to target benefits to countries and communities that conserve their biodiversity and make it available for biodiversity prospecting? Second, how can countries build the research and commercial capacity to make use of their own genetic resources? The Convention on Biological Diversity addressed these issues by reaffirming the sovereign rights of nations to their biodiversity, establishing the right of nations to regulate access to genetic resources, and creating technology-transfer mechanisms. The legal aspects of regulating genetic access are discussed in 13.6.3.1.

13.3.7 Managing the impacts of tourism on biodiversity

Tourism has become one of the largest economic activities in the world – if not the largest. In developing countries alone, it

generated US\$62.5 billion in 1990. Throughout the world, international arrivals of visitors were estimated at nearly 450 million people in 1990, generating nearly US\$3.5 trillion. This amount is greater than that generated by the global agriculture, automobile or steel manufacturing industries (WTO 1991, 1992). The rapid growth in tourism has produced more infrastructure, increased pollution, put unsustainable demands on local environments, and created adverse impacts on biodiversity. In many coastal areas, for example, strings of high-rise hotels stretch for kilometres along beaches that not long ago might have been diverse habitats of coastal forest, mangroves, seagrass beds and coral reefs.

But tourism, particularly ecotourism or nature tourism, is also seen as a force to help the sustainable use and protection of biodiversity, since the wildlife and natural habitats that draw visitors also generate significant income and foreign exchange in some parts of the world. And this influence will increase, as nature tourism is one of the fastest-growing elements of tourism, increasing at a rate of 7% annually (Filion *et al.* 1992). In Kenya, for example, tourism is the country's largest earner of foreign exchange: nearly all its visitors come to visit the national parks and view wildlife (McNeely *et al.* 1992). Nature tourism is also a tremendous economic force in Costa Rica and a growing number of other countries, and may be valued at US\$50 billion world-wide by the turn of the century. Tourism, therefore, is both a benefit and a curse to the sustainable use and protection of biodiversity.

The big challenges in minimizing the impact of 'mass tourism' on biodiversity lie with problems such as sewage treatment in coastal areas, site selection of hotels, pollution caused by large fleets of tour buses, impacts of scuba divers on coral reefs, and environmental issues posed by golf courses, waste treatment of big resort hotels, etc. Ecotourism can contribute to pressures on biodiversity through serious trail erosion, cutting down trees for fuelwood, inappropriately sited infrastructure in protected areas, and waste disposal (see also 13.5.3.3). While these may occasionally seem peripheral to the management of biodiversity, they have caused significant local losses of biodiversity in many parts of the world and – at least indirectly – have contributed to the global endangerment of species. One basic step towards protecting biodiversity from unintended adverse impacts associated with tourism is to use environmental impact assessment (EIA) procedures to identify serious problems before they occur. Siting is the most important consideration in the EIA process. For example, in fragile island environments, all tourism facilities should be placed well away from sensitive habitats (e.g. seabird and turtle nesting areas, mangrove forests, salt ponds, seal and sealion rookeries) and well above the high-water mark since natural erosion and accretion cycles are a feature of many beaches. Careful planning, design, and building guidelines for tourism

facilities are required to ensure that tourism enhances rather than detracts from the natural setting. Further, the capacity of facilities and the projected number of visitors need to be assessed relative to the management objectives of each area, particularly the need to avoid damaging the site (Ceballos-Lascurain 1993).

In addition to considering the impacts of major hotel and resort complexes, it is important to assess the impact of adjacent developments, such as golf courses or marinas, designed to serve visitors. Guidelines for golf course design and construction should include provisions to avoid clearing native forests for new golf-course development, and to replant with native trees, shrubs and grasses whenever possible. Marinas should not be built in sensitive habitats, where dredging or changes in water circulation could displace rare or migratory species. Once facilities have been built, it is important to monitor their impact, and that of the users, on indicators of wildlife, habitat or environmental quality identified during the EIA process. Using this information, damaging activities can be reduced before they become critical (McIntyre 1993).

In coastal areas, waste disposal can create serious problems for coral reefs and other marine habitats, not to mention human health (Salm and Clark 1984). Experience has now shown that there is no completely safe method of waste disposal. All forms of disposal can have negative impacts on the environment, public health and local economies. In particular, many water and waste-water treatment systems load aquatic habitats with excess nutrients that stimulate unnatural levels of algal growth, killing native species and reducing local biodiversity. Pollution prevention, through reducing the amount of waste produced, is the most effective way of avoiding many of these problems. In addition, an emphasis should be placed on using products that minimize waste and are non-toxic, on recycling materials, and on composting biodegradable wastes.

13.3.8 Managing impacts of urbanization and infrastructure on biodiversity

The land area occupied by cities, towns and infrastructure (e.g. highways, airports, canals, railroads, etc.) has grown dramatically in many parts of the world during the second half of the twentieth century. While the total area is small – built-up areas generally occupy less than 5% of the total land area in European countries (WRI 1994) – the infrastructure and urban areas of growing societies do have substantial impacts on biodiversity (see also Section 11). Land-use planning and environmental impact assessment practices and other actions, however, can minimize the impacts of urbanization on biodiversity.

13.3.8.1 Conserving biodiversity in urban areas

Urban environments and biodiversity are often seen to be mutually exclusive. Some authors deliberately exclude the

biodiversity associated with urban parks, street and roadside plantings, and household yards and gardens, on the grounds that it is artificial (Angermeier 1994). A growing number of researchers, however, are working to inventory, restore and protect biodiversity in city and suburban landscapes (e.g. Soulé 1991; Goode 1993; Beatley 1994). Urban conservation, which was a minor interest of conservationists in the 1960s and 1970s in Europe and the United States, is now becoming a major movement (Heywood 1995). Today, there is a substantial literature on urban landscapes and their wildlife (e.g. Beissinger and Osborne 1982; Kalpavriksh 1991; López-Moreno 1993; Jordan 1994).

In many parts of the world, especially in developed countries, a majority of the population lives in urban areas. This is the case in a growing number of developing countries as well. The urban population in 1995 reached 45.2% of world-wide population, and nearly 20% of all people lived in major cities with populations over 750 000 (WRI 1994). The range of urban population varies considerably, from 100% in Singapore and in the 60–80% range for most OECD countries, to less than 10% in a handful of countries in Africa (e.g. Rwanda, Burundi) and Asia (Bhutan). By 2025, the UN (1989) estimates that 80% of residents in developed countries will live in cities: world-wide, at least 60% of the population will live in urban areas.

Within these cities, a diverse range of artificial, semi-natural and natural habitats exist. These include urban parks, botanic gardens, nature reserves, university and business campuses, cemeteries and a wide range of other urban ‘green spaces’ (Heywood 1995) (Table 13.3-1). In the United States, parkland ranges from 42% in Honolulu to 0.3% in Baton Rouge (WRI 1994). In Europe, about 20% of cities and towns are devoted to open space.

13.3.8.1.1 Habitat types. Some cities have within their boundaries remnants of native vegetation, sometimes even extensive areas; for example, remnants of the celebrated Mata Atlantica forests are found in Rio de Janeiro, Brazil (Monteiro and Kaz 1992). In Portland, Oregon, just 3 kilometres from the urban centre is Forest Park, a 4000 hectare forest area with a virtually complete inventory of plants and wildlife found in larger natural forest areas outside the city. Within the city of Caracas, Venezuela, the National Park El Avila protects the majestic wall of mountains on the city’s north side and provides a home to over 1700 species of flowering plants (Steyermark and Huber 1978). The Singapore Botanic Garden is a celebrated but small patch (4 ha) of original tropical evergreen forest in centre of the world’s second busiest port city (Tinsley 1983). Many other cities have examples of surviving natural habitats, including the forests found on the campus of York University in Toronto, Canada, and the Ridge Forest in Delhi, a 7700 ha sliver of wild and manicured vegetation running through the heart of the city of 8 million people (Kalpavriksh 1991).

Table 13.3-1: Types of urban 'green spaces'.

National parks	Nature reserves
Municipal parks	Domestic gardens
Botanic gardens	Roadside verges
Zoological gardens	Greenways
Arboreta	Plant nurseries
Wildlife corridors	Industrial parks
Urban commons	Cemeteries
Business parks	Golf courses
Canals	Street trees
Streams and ponds	Urban forests
Nature centres	Garden centres
Vacant lots	University campuses

Abandoned industrial land, old quarries, untended roadways, railroad corridors and other unkempt areas exist in nearly all cities. In many cases, these areas have become new semi-natural habitats that support a diversity of plant and animal life. Mabey (1973) calls these areas the 'unofficial countryside'. Goode (1993) suggests that abandoned and derelict lands in urban areas provide opportunities for creating habitats and enhancing urban biodiversity. Habitat restoration and rehabilitation is taking place in urban and suburban areas to generate new value and benefits from abandoned lands and semi-natural areas (see 13.4.4 for ecosystem restoration and rehabilitation measures). Finally, human-made habitats are diverse in most urban landscapes. Within cities, vineyards (e.g. on the butte de Montmartre in Paris), agricultural fields and home gardens, urban landscaping, intensive horticulture (e.g. the Huerta in Valencia, Spain), recreated wetlands (e.g. Utrecht, Netherlands), historical sites and a wide range of other habitats contain hundreds or up to several thousand cultivated plant species and a more limited diversity of native plants, birds, and other fauna.

13.3.8.1.2 Species diversity in urban habitats. While urban habitats have been the subject of an increasing amount of biological inventory work, the data do not allow conclusions about the overall biodiversity of urban habitats in any particular city, let alone on a world-wide basis. Still, evidence of the enormous diversity of such habits is coming to light. In Italy, for example, advanced ornithological studies have been carried out in 27 towns and cities, and nearly 600 papers have been published on Italian urban avifauna. Dinetti (1994) records 103 breeding species of birds in Italy's urban areas. In Dehli, 400 bird species – one-third of India's total avifauna – have been recorded. These include representatives of almost every major bird family, and birds typical of almost every major

ecosystem: forest, wetland, grassland and desert (Kalpavriksh 1991).

While many of these species are introduced, the number of native or migratory species found in urban areas can be surprisingly high. In the case of higher plant species, more than 50% of recorded species in cities as different as Mexico City and Rome are native. In the Netherlands, about 50% of the country's native flora – including nearly 20% of the country's rare species – can be found growing along roadside margins and rights of way (Sykora *et al.* 1994).

In many cities, thousands of exotic species are cultivated in public and private parks and gardens. Botanic gardens, for example, are usually found in cities, and together they maintain at least 80 000 of the world's estimated 250 000 plant species. This represents the greatest plant diversity outside nature. Private gardens, especially those of specialist collectors, also maintain thousands of additional species. The scientific, educational and cultural value of this large sample of the world's flora found in cities should not be underestimated. Most of this cultivated and introduced plant diversity does not form breeding populations. As a result, its genetic diversity is usually not very good. The intensive breeding and selection that take place in public and private botanic gardens and horticultural centres, however, create large amounts of new genetic variation in the form of cultivars and varieties of ornamental plants (e.g. orchids, narcissus, tulips, roses, begonias, delphiniums, polyanthus, pansies, violas, etc.).

13.3.8.1.3 Actions to conserve urban biodiversity. The urban conservation movement is pushing governments and planners around the world to take steps to maintain – or create – habitats within urban ecosystems for wildlife and ecosystem services. In New Dehli, the Ridge Forest has faced a series of familiar threats: construction, road-widening, garbage dumping and quarrying. Pressured by concerned citizens, especially school groups, local residents and organized community groups, Delhi's Lieutenant Governor recently appointed a task force to develop a management plan for the Ridge Forest (Delhi Administration 1994). The Delhi administration has now declared the entire Ridge Reserved Forest under the Indian Forest Act, and has declared its intention not to allow any further diversion for non-forest purposes. In Calcutta, one of the most densely populated cities in the world (35 000 km²), environmentalists have organized to protect the city's limited green space (4% of total land area). This small area harbours at least 20 small- and medium-sized mammalian species, 150 bird species, over 10 amphibians and over 100 species of butterflies (Ghosh 1989).

A number of European cities including Edinburgh, Scotland and Moscow, Russia have developed Urban Nature Conservation Strategies. UNESCO has established a Man and the Biosphere Project (number 11) on urban systems, and journals such as *Urban Wildlife News* in the

United Kingdom and *Urban Forests* (published by American Forests) are reaching a rapidly growing number of conservationists working to maintain biodiversity in city landscapes. The bioregional approach to the protection and use of biodiversity advocated in the *Global Biodiversity Strategy* (WRI/IUCN/UNEP 1992) encompasses urban and suburban landscapes and recognizes the contribution urban ecosystems can make to biodiversity conservation. Conservation biology (e.g. use of corridors, selection of priority conservation areas, etc.) is increasingly being used to guide regional and urban planning in the United States (Soulé 1991; Beatley 1994) and elsewhere.

Perhaps the most important reasons to use and protect biodiversity in urban landscapes are the educational, aesthetic and moral values it can provide to the urban societies in which most of the world's people will soon live. As Box and Harrison (1994) have noted:

If the contribution of urban green spaces to future generations is to be justified solely in terms of their contribution to the stock of environmental assets, then urban environmental assets will always be deemed to be poor substitutes for their rural counterparts. On the other hand, if urban green space policies acknowledge the social and educational assets of accessible natural green spaces, then the inheritance value of these areas is unrivalled.

13.3.8.2 *Managing the impacts of infrastructure on biodiversity*

Infrastructure projects, whether roads, dams, port facilities, power projects or pipelines, can have a dramatic impact on biodiversity. Roads through forests or canals through wetlands can have an impact that goes far beyond the immediate project boundaries. For example, Lanly (1982) estimated that tropical forest areas with road networks were eight times more likely to be deforested (from agricultural conversion) than are roadless forest areas. The value of intact forest for carbon sequestration, sustainable forest management for timber and other products, ecotourism, water supplies, and other products and services, may far outweigh the costs of building a longer road through degraded or converted habitats.

Land-use planning and environmental impact assessments are the principal tools for avoiding or minimizing the adverse impacts of infrastructure development on biodiversity (see also 13.6). The widespread adoption of environmental impact assessment policies in countries around the world provides new opportunities for addressing biodiversity protection and management in many mainstream development projects. Although it is rare for such projects to be abandoned because of their impacts on biodiversity, it is increasingly common for protection and mitigation methods to be adopted as a consequence of these impacts.

Methods can range from the conservation of a natural habitat area as compensation for an equivalent area lost to a project, to the improved management of watersheds that both maximizes the life of a hydroelectric dam by reducing soil erosion and conserves forests and their biodiversity (World Bank 1995).

Two examples of 'mainstreaming' biodiversity conservation in infrastructure development projects are being supported by the World Bank (World Bank 1995). In Ghana, urbanization and related infrastructure development in greater Accra and other coastal towns threaten coastal lagoons that provide livelihood opportunities for local residents and a critical refuge for tens of thousands of migratory birds. Without making biodiversity conservation an explicit objective of infrastructure development, the pressure of sewage and industrial effluent would rapidly degrade wetland habitats. World Bank and Global Environment Facility (GEF) assistance is being provided to redesign sewage treatment and effluent disposal methods, reduce recreational pressure on lagoons, and support community initiatives to use the lagoons' biological resources sustainably.

In Grenada, a landfill site was proposed for an area containing one of only two populations of the endangered Grenada dove. World Bank and GEF assistance is now being used to redesign and relocate the landfill and help with local Grenada dove conservation efforts.

The World Bank now has provisions to address potential impacts on biodiversity in several environmental policies (e.g. Natural Habitats, Forestry, Environmental Assessment, Water Resources Management, Agricultural Pest Management, and the Environmental Policy for Dam and Reservoir Projects). These are applied to virtually all infrastructure projects financed by the Bank. Other development agencies have adopted similar policies, although it is not clear how effectively they are being implemented.

13.3.9 *Conclusion*

Our ability to maintain and make the most beneficial use of biodiversity depends on using and managing biodiversity sustainably in agriculture, forestry, fisheries, tourism and other activities where the production of goods and services for human consumption is the principal objective.

Many traditional agricultural management systems provide opportunities for the conservation and sustainable use of biodiversity. For example, small-scale farmers using traditional agricultural practices have long been effective creators of varietal diversity and stewards of genetic diversity: traditional forms of agriculture, particularly in developing countries, are the world's largest repositories of crop and livestock genetic diversity. Farmers cannot continue to provide this 'service' to others, however, in regions where conversion to high-input, low-diversity agroecosystems is economically more advantageous. As a

result, much of the genetic diversity associated with traditional systems will continue to decline rapidly without funds or market mechanisms to compensate local farmers for this service.

Modern agriculture has been a major beneficiary of biodiversity, particularly the varietal diversity generated in traditional agriculture. Modern agriculture has offered tremendous gains in productivity through technological innovation and the widespread adoption of uniform, high-yielding varieties. Future gains in productivity will depend on improved management of genetic resources in time (e.g. gene banks) and space (e.g. crop variety mosaics). While we have an incomplete understanding of the magnitude of potential future losses in crop productivity due to the narrowing of the genetic base for breeding, genetic vulnerability of many of the world's most important food crops and animals appears to be growing.

To meet the demands of a growing world population and simultaneously maintain biodiversity requires measures that (1) conserve genetic diversity in existing domesticated plant and animal varieties, (2) identify and conserve wild species that can improve agricultural productivity and adaptability in the face of environmental change, and (3) minimize the adverse impacts of agricultural practices on other ecosystems.

Traditional approaches to forest and fisheries management have also – intentionally or unintentionally – contributed to the maintenance of biodiversity but, as in agriculture, traditional practices are disappearing rapidly. The intensification of forestry and fisheries management has led to dramatic increases in yield. This, however, has caused significant interventions in natural disturbance regimes and species composition and consequent reductions in biodiversity in many forestry and fisheries production areas.

Resource management practices that allow or emulate natural disturbance patterns will tend to be more supportive of biodiversity. For example, forestry practices that mimic natural disturbance regimes such as fire, wind blow-downs, and pathogen outbreaks, appear to offer the best opportunities for maintaining the biodiversity associated with forest ecosystems. In fisheries, better monitoring of fish stocks, the use of dynamic models that incorporate interactions between fish stocks and environmental factors, and the use of more selective fish capture methods offer hope for increasing the sustainability of the harvest and the conservation of marine biodiversity.

Social and economic measures, however, may be much more important than technical measures for ensuring sustainable use (see Section 12 and 13.5).

13.4 Protecting and restoring ecosystems, species, populations and genetic diversity

13.4.1 Introduction

The sustainable use methods discussed in 13.3 are essential steps toward conserving the world's biotic wealth. Some species are best conserved within sustainable use systems because these confer value and provide direct economic incentives. However, it is not possible to maintain all elements of biodiversity within forestry, fisheries, agriculture and other systems where humans extract or directly manipulate biological resources. For example, many species, including wild relatives of commercially important species, occur in habitats of limited direct utility for agriculture, forestry or even consumptive wildlife cropping. Managing the overall diversity of genes, species and ecosystems, therefore, also requires actions to set aside some areas as nature reserves and to place rare or endangered species and genetic resources in *ex situ* (off-site) facilities, ideally with a view to the restoration of wild habitats. This chapter assesses a wide range of methods associated with conservation systems (e.g. protected areas and natural habitat management, restoration ecology, zoos, botanical gardens, museums, seed banks and germplasm-

storage facilities) in which the preservation of biodiversity is a principal objective. These methods are, in a sense, insurance against the limitations of the sustainable use approaches presented in the previous chapter.

13.4.2 Protecting ecosystems

In most definitions of biodiversity (see Sections 1 and 2), ecosystems represent the highest level of biological interaction. Because biological communities, species, populations, genes and the biogeochemical processes that sustain life are all represented in the concept of the ecosystems, many conservation efforts emphasize methods of protecting ecosystems. These methods seek to regulate human activities in geographic areas where they may adversely impact populations of species or interfere with ecosystem processes (e.g. fire and other natural disturbance regimes) upon which a given ecosystem's biodiversity depends. One of the major goals in conservation biology is to protect a representative array of ecosystems and their constituent biodiversity. In addition to protected area measures, ecosystem protection methods also include efforts to maintain habitat fragments and corridors in human-dominated landscapes, and to protect or mimic specific ecological processes (e.g. hydrologic regimes) important to an area's biodiversity.

13.4.2.1 Protected areas

A protected area is defined by the Convention on Biological Diversity as 'a geographically defined area which is designated or regulated and managed to achieve specific conservation objectives'. At the Fourth World Congress on National Parks and Protected Areas, held in Caracas, Venezuela, in 1992 (IUCN 1994b), such protected areas were defined as areas 'of land and/or sea especially dedicated to the protection and maintenance of biological diversity, and of natural and associated cultural resources, and managed through legal or other effective means'. The *Global Biodiversity Strategy* (WRI/IUCN/UNEP 1992) defines a protected area as 'a legally established land or water area under either public or private ownership that is regulated and managed to achieve specific conservation goals'. Whatever the precise definition, protected areas have figured prominently in biodiversity conservation efforts around the world.

Nearly 10 000 protected areas are recognized by the IUCN Commission on Parks and Protected Areas. These areas are managed for objectives ranging from strict preservation to controlled resource harvesting. All contribute in some way to conserving biodiversity, but modifying the management and selection of protected areas will enhance their contribution. Explicit biodiversity conservation objectives need to be established for each protected area, and in most cases, they need to be better integrated into the fabric of social, environmental and economic welfare

(WRI/IUCN/UNEP 1992). If protected areas are to become more effective in maintaining biodiversity, serious obstacles must be overcome, including, among others:

- inadequate biogeographic distribution;
- conflicts with local peoples;
- ineffective management and funding, and
- a limited appreciation of potential roles in sustainable development.

13.4.2.1.1 Protected area classification, size, and distribution. An overview of the world's protected area systems is given in Table 13.4-1. This gives the extent of protected areas in square kilometres and the percentage coverage in each of the geopolitical regions recognized by the IUCN Commission on National Parks and Protected Areas (CNPPA). These data are drawn directly from the 1993 *United Nations List of National Parks and Protected Areas* (IUCN 1994a), which provides an internationally recognized definition of the global protected area system.

Three criteria govern whether or not a protected area is included in the UN List: size, management objectives, and the authority of the management agency:

Size. For practical reasons, only protected areas of more than 10 km² are included, with the exception of offshore or oceanic islands of at least 1 km² where the whole island is protected.

Management objectives. A series of protected area management categories, defined by management objective, was identified by IUCN/CNPPA in 1978: these have been revised since the 1993 UN List was published (IUCN 1994b). IUCN Management Categories are applied irrespective of national names for protected areas. Categorization is by primary management objective and assignment to a category is not a commentary on management effectiveness.

Authority of the management agency. In the past, only those sites managed by the 'highest competent authority' were included in the UN List, i.e. those within the highest appropriate level of government. In the current edition of the List, those sites managed by state or provincial authorities within federal systems have also been included.

The UN List therefore represents a subset of the 37 000 protected area sites recorded in the WCMC (World Conservation Monitoring Centre) protected areas database. As of 1994, 9832 protected areas qualify under the above criteria for inclusion in the UN List.

^a IUCN management categories are given in Box 13.4-1.

^b Percentage figure reduced to zero due to rounding.

^c Percentage figure inflated because land area is used in calculation whilst Great Barrier Reef Marine Park (343 800 km²) is marine.

^d Pacific includes New Zealand, in line with recent re-definition of CNPPA Regions.

Data source: 1993 United Nations List of National Parks and Protected Areas (IUCN 1994a)

The growth in the number of protected areas and their area has been dramatic during the past 30 years, although the rate of growth has slowed considerably since 1980 (see Figure 13.4-1). Information for the 1993 UN List was gathered by WCMC from management agencies during the course of 1993, in collaboration with IUCN. Three important types of protected areas – forestry reserves, private nature reserves and other protected areas, and indigenous reserves – have not been included in the UN List, either because the areas do not meet the criteria or because available information is incomplete. Nevertheless, the contribution of these three sectors to conservation and sustainable development is considerable.

The extent of protection varies widely from one region to another, from 2.8% of land area in North Africa and the Middle East (IUCN’s classification recognizes a small area in Category I for Antarctica, although the entire continent was recently dedicated to ‘science and peace’) to 12.6% in North America. These aggregated figures disguise variation within a region. For example, in Europe, Austria has nearly 25% of its land area within protected areas, while Greece has less than 2%.

Figure 13.4-2 depicts the distribution of protected areas across a range of size classes. In general, there is a large number of relatively small protected areas and a limited number of very large sites. Only four sites cover more than 100 000 km² apiece, but between them they cover 1.7 million km², a large proportion of the global total (approximately 17%). The largest protected area in the world, Greenland National Park at 972 000 km² accounts for more than 10% of all the area protected. The large number of smaller sites should not be dismissed, however, because many are carefully located to protect specific habitats, species or other areas of conservation concern. Many nations, for example in the Pacific and Caribbean, do not have the territory to establish extensive terrestrial protected areas, and many of these sites are excluded from these data on the basis of the 10 km² minimum-size criterion.

Definitions of the IUCN Protected Area categories are shown in Box 13.4-1. Figure 13.4-3 illustrates the much higher prevalence of Category IV sites (Managed Nature Reserve), even though Category II (National Park) covers a

Figure 13.4-1: Growth of the global protected areas network (non-cumulative). (Source: McNeely *et al.* 1994.)

greater area. Again there is a strong degree of regional variation. Category V (Protected Landscape) is widely used in Europe where there is little opportunity to set aside extensive, strictly protected tracts of land. On the other hand, precisely those opportunities have existed in South America, where half of the protected area system is classified as more strictly protected Category II sites. Although Category I and II reserves cover almost 4% of Australia’s landscape, many major ecosystems are poorly represented. Areas in the recently created Category VI (Managed Resource Protected Areas) are not included in this summary.

Two key aspects are not revealed in these summary statistics: management effectiveness and threats to protected areas. Although global, systematic data are not available, there is clear evidence that a large proportion of protected areas have yet to be implemented on the ground (IUCN 1992). Inadequate legal and institutional support, and insufficient manpower and financial resources, result in many areas receiving a less-than-satisfactory level of protection. Allied to this is the number and severity of threats faced by protected areas, including development pressures, unmanaged tourism, poaching, and so on. Thus the data in Table 13.4-1 indicate the quantity, but not the quality, of protected areas.

In addition to listing protected areas according to their geopolitical distribution, it is also possible to analyse their biogeographical distribution. Protected areas included in the UN List have been located within one of the biogeographical provinces defined by Udvardy (1975),

which divide the world into eight realms, subdivided into 193 provinces, with each province being characterized by one of 14 biome types. Of the 9832 protected areas qualifying for inclusion, 8564 are classified by the Udvardy province in which they are located. The remaining 1268 sites, including a large number of marine sites, cannot be classified within this system.

Table 13.4-2 provides a summary of protected area coverage (number of sites, area protected, percentage of realm protected) for each of the eight realms recognized by Udvardy (1975). In terms of the 10% protected-areas coverage target established by IUCN for each realm, only the Nearctic Realm (Mexico, the United States, Canada and

After Udvardy 1975; source: IUCN 1994a.

Box 13.4-1: 1994 IUCN Revised Protected Area Categories.

Category I: Strict Nature Reserve/Wilderness Area. To protect nature and maintain natural processes in an undisturbed state in order to have ecologically representative examples of the natural environment for scientific study, environmental monitoring, education and maintenance of genetic resources in a dynamic and evolutionary state. There are two sub-categories: Ia includes protected areas managed mainly for scientific research and monitoring; Ib includes protected areas managed mainly for wilderness protection, subsistence and recreation.

Category II: National Park. To protect outstanding natural and scenic areas of national or international significance for scientific, educational and recreational use. These are relatively large areas not materially altered by human activity and where extractive resource uses are not allowed.

Category III: National Monument/Natural Landmark. To protect and preserve nationally significant natural features because of their special interest or unique characteristics. These are relatively small areas focused on the protection of specific features.

Category IV: Habitat/Species Management Area. To assure the natural conditions necessary to protect nationally significant species, groups of species, biotic communities or physical features of the environment where these may require specific human manipulation for their perpetuation. Controlled harvesting of some resources may be permitted.

Category V: Protected Landscapes and Seascapes. To maintain nationally significant natural landscapes that are characteristic of the harmonious interaction of man and land while providing opportunities for public enjoyment through recreation and tourism. These are mixed cultural/natural landscapes of high scenic value where traditional land uses are maintained.

Category VI: Managed Resource Protected Area. This is a new category designed to include areas that ensure long-term protection and maintenance of biodiversity while providing a sustainable flow of natural products and services to meet community needs. They are intended to be relatively large and predominantly unmodified natural systems where traditional and sustainable resource uses are encouraged.

Source: IUCN (1994b).

Greenland) is adequately protected. Data at the level of the 193 individual Udvardy provinces (not given here; see IUCN 1994a) show that approximately 25% of biogeographical regions appear to have more than 10% of their area protected.

There are, however, limitations to using the Udvardy system to analyse the biogeographic representativeness of the world's protected areas. This is due both to its relative imprecision and, for example, differences in size between provinces. A 5000 hectare protected area in the relatively small Malagasy Thorn Forest province on Madagascar, for example, would protect a much larger section of that province than a reserve of equal size in the huge Somalian province of northeast Africa.

While the results are sufficient to illustrate patchy coverage, more detailed analysis is necessary to determine real needs and priorities. Efforts to identify such priorities have been conducted by the IUCN Commission on National Parks and Protected Areas (CNPPA) for Indo-Malaysia (MacKinnon and MacKinnon 1986a), sub-

Saharan Africa (MacKinnon and MacKinnon 1986b) and Oceania (Dahl 1986). More recently, the CNPPA completed regional reviews for the world's protected areas that were presented at the Fourth World Congress on National Parks and Protected Areas in Caracas, Venezuela, in February 1992. After the Congress, these reviews were revised and published (see McNeely *et al.* 1994).

Table 13.4-3 provides a summary of protected area coverage (number of sites and total area) by biome type. A biome is a major portion of the living environment of a particular region (such as coniferous forest or grassland), characterized by its distinctive vegetation and maintained by local climatic conditions. Protected area coverage of biomes ranges from as low as 0.69% in temperate grasslands, to a little under 10% in subtropical and temperate rainforests ('mixed island systems' have greater protection but this category – along with 'mixed mountain systems' – is frequently criticized for being too general), again providing broad guidelines for the location of additional protected areas.

Figure 13.4-2: Size distribution of protected areas in the 1993 *UN List of National Parks and Protected Areas*. (Source: IUCN 1994a.)

Summarizing the coverage by biome gives a first approximation of how well the major ecological formations are legally protected. There is again considerable variation of protection within biomes and a wide range in the actual management effectiveness of individual protected areas. It is important to recognize that biome type does not mean the same as habitat type; a protected area within a tropical humid forest biome may not necessarily contain tropical humid forest, and an area containing tropical humid forest could occur in another biome altogether (such as mixed island systems). Note in this regard that Udvardy identifies all of Indonesia, insular Malaysia, and the Philippines as mixed island systems rather than tropical humid forest. Also, as was noted above for provinces, there are significant differences between the areas covered by different biome types. For example, in the Neotropics the tropical humid forest biome covers an extensive area (about a quarter of the continent), while the lake systems biome covers only a small area (e.g. Lake Titicaca on the Peru/Bolivia border). It should also be noted that these are aggregates of protected areas with different management objectives – not all areas are protected to the same degree, as discussed below.

13.4.2.1.2 *Managing biodiversity in protected areas.* Protected area designations, as explained above, are legal, policy or traditional mechanisms by which society can

establish regimes for land/sea management to maintain and protect plant, animal and cultural resources of particular value. They are packaging devices to help assemble and apply the necessary means to achieve defined ends. In nearly all protected areas, some uses (e.g. scientific research and non-consumptive ecotourism) are allowed, and in many protected areas, various sustainable uses of renewable resources are permitted.

All six types of protected areas, as categorized by IUCN (see Box 13.4-1), provide distinct land-management systems with the potential to conserve biodiversity while at the same time meeting other objectives. The utility of employing a systematic classification lies in its fostering a rigorous determination of the objectives of management, the geographic placement in the landscape/seascape, and the means or measures that are to be employed. By this relatively universal approach, the Strict Nature Reserve/Wilderness Area, for example, is employed where objectives focus upon the maintenance of relatively wild habitats and ecosystems for the purpose of retaining samples of a nation's various natural environments, e.g. forest types, grasslands, mountain ranges, coastal formations and coral reefs. Assigning a site to this category makes explicit the government's intention to maintain biodiversity in the area and to promote knowledge and understanding of the site's resources. It also makes explicit

Figure 13.4-3: Number and extent of protected areas by IUCN Management Categories. (Source: IUCN 1994a.)

that other possible uses of the same area for agriculture or timber extraction, for example, will be forgone.

At the other end of the spectrum of protected area types, the Protected Landscape/Seascape category seeks to maintain an entire set of ecosystems that have been significantly shaped by people over time and have acquired cultural value. Generally, these areas feature older land-use practices and/or cultural structures or remains that societies want to retain. This management system seeks to encourage rural and town residents to remain in the area and fosters land-use practices that deliberately retain selected landscape features (e.g. hedgerows in the United Kingdom) or the restored ancient or traditional architecture and structures (e.g. Machu Picchu and Cuzco, Peru). These types of areas can also feature the retention and nurturing of biodiversity on farms and around villages (Altieri and Merrick 1987; Ghosh 1993; see 13.3.2).

A new category, Managed Resource Protected Areas, was created in 1994 to recognize that many areas are

protected in order to maintain the ability of traditional and local communities to sustainably use biological resources within relatively unmodified natural landscapes. For example, extractive reserves in Brazil have been established to protect natural forest areas used by rubber tappers, Brazil-nut harvesters and others from being converted to agricultural or plantation uses which would preclude the harvesting of natural forest products.

These management systems are administered predominantly by the highest level of government, hence the nomenclature of national park, national monument, national reserve, etc. Alternatively, other levels of government (state, province, county) and private interests (NGOs, communities, indigenous traditions) have established protected areas which they administer. Examples include the state parks of the United States, the provincial parks of Canada, the community forests and grazing lands of Africa, and the sacred forests of India, Indonesia and the Amerindians of the Western Hemisphere, the vast network of private reserves of The Nature Conservancy in the United States and rapidly expanding networks of private nature reserves in Brazil, Colombia and Paraguay.

13.4.2.1.3 Defining management objectives. The design of areas protected principally for biodiversity preservation, or those managed for biodiversity and other compatible objectives, begins with two fundamental steps: defining the management objectives for the area, and the actual selection of a site.

A desire to maintain a sample of a particular biome with disturbances limited to natural forces and the necessary scientific interventions may preclude resource extraction on that site. Elsewhere, human interaction with the site may be long, intensive and traditional. In these cases, the biodiversity to be conserved may require continuing intervention through farming, fire, extractive use of the forests or grazing. Here, management systems will be designed to fit the context. They may feature co-operative management and possibly co-operative finance programmes with local people, be they neighbours of the reserve or its residents (e.g. North Yorkshire Moors, UK, see Statham 1994; the Chico Mendez Extractive Reserve, Brazil, see Hecht and Cockburn 1989).

Two issues are fundamental to the selection of management categories:

1. Trade-offs are a necessary feature of establishing a management system in a defined area. Only by clarifying the objectives and relating those to an assessment of the status and trends of the site can decision-makers (agency directors, community leaders, scientists) determine the 'best mix' of means and ends. If biodiversity is the objective, then other possible commitments and uses will be shaped around this dominant purpose. Alternatively, if watershed

Table 13.4-3: Distribution of protected areas by biome type.

Blome type	Area (km ²)	Number	Area (ha)	%
Tropical humid forests	10 513 210	506	53 833 388	5.1
Subtropical/temperate rainforests/woodlands	3 930 979	899	36 629 731	9.3

Evergreen selerophyllous forests	3 757 144	776	17 758 448	4.7
Warm deserts/semi-deserts	24 279 842	300	98 400 670	4.1
Cold-winter deserts	9 250 252	136	36 472 009	3.9
Tundra communities	22 017 390	78	164 504 267	7.5
Tropical grasslands/savannahs	4 264 833	59	23 512 784	5.5
Temperate grasslands	8 976 591	194	9 998 248	0.8
Mixed mountain systems	10 633 145	1277	85 249 420	8.0
Mixed island systems	3 252 270	530	32 276 920	9.9
Lake systems	517 694	17	663 486	1.3

Protected areas are excluded from the above analysis if location is unknown. Based on 1992 data. Source: IUCN (1994a).

- restoration, tourism, or extraction for rural people are the dominant ends, then biodiversity management will be the goal that is limited and shaped.

2. Conserving biodiversity *in situ* as an objective may not always be consistent with purposes that include maintaining the ‘wilderness’ character of an area together with free-ranging recreation or tourism, and it will certainly be at odds with the use or introduction of exotic species, especially in cases of restoration and rehabilitation work.

The second key step is the actual selection of the site. With the general objective determined (e.g. protecting a representative sample of a coastal wetland type, maintaining several breeding populations of an endangered antelope, or preserving an area that features an important strain of wild rice), the appropriate geographic site can be selected. This determination should include factors such as: the species, populations and communities desired; land/or sea area (size) needed to include a range of habitat types, patch dynamics, and ecosystem processes; and places for the necessary installations and facilities. Methods to maximize biodiversity captured in the process of site selection have become increasingly sophisticated (e.g. Margules *et al.* 1988; see also 13.2).

Typically, countries will face a more practical challenge. How can existing protected areas be managed in order to maintain biodiversity adequately? Two types of problems arise:
- Existing parks and reserves may already be committed to other dominant purposes such as tourism or some form of natural resource extraction. In these cases, a research programme (see below) can be used to readjust an area’s objectives, zoning and installations, and even its management category.
 - The area may be adequate for its original objective, but subsequent improvements in scientific knowledge and shifts in social goals that favour biodiversity management may call for adjustments in the size and shape of the reserve to include habitats and sites critical for specific species, migration, pollination, stream flow and other ecological factors.

Ideally, revising a site’s management plan by agency and community leaders and scientific personnel will identify opportunities for extension of the area where needed and the application of restoration techniques (see 13.4.4).

Ten generally supported guidelines can be listed to guide the establishment or replanning of protected areas that will have biodiversity conservation as their central or major purpose:

 - Number of areas.** A larger number of sites will provide better coverage of the diversity of habitats and transition areas in the country. The larger number will also cover the need for redundancy as protection from disease and catastrophic natural or anthropomorphic disturbance or social upheaval. Having a single reserve in each

biological region of the country is risky for these reasons.

2. **Size.** Ideally, each area should be as large as needed to embrace the biota of concern, together with the related habitats and ecosystem factors. Naturally, both number and size will be co-determined by social and economic factors in terms of habitation density, occupancy by local human residents, availability of agricultural soils, and internal demand for food and material production from these same areas.
3. **Interconnectedness.** The intervening landscape or water areas should permit the flow of biota from site to site in response to daily and seasonal changes (e.g. migration), climate change, and other large and small spatial and temporal-scale factors. The establishment of corridors between protected areas and other natural habitats is discussed in 13.4.2.2.
4. **Zoning.** Within the selected area, designation of various zones can segregate management objectives and uses that may be incompatible and identify management activities by area. Areas of key significance for their genetic materials may well be zoned out of human visitation. Scientific research sites may warrant special protection. Places of high value for education and recreation will require installations, trails and transportation. These zones for public access will perhaps have less potential for protecting certain features of biodiversity, but can maximize other legitimate goals of the reserve (Miller 1980).
5. **Location of facilities and infrastructure.** The design of trails and roads, buildings and infrastructure (fuel, sewage, water, power) can affect biodiversity. Physical development, even those limited facilities required by most protected areas, should be designed and located as part of the overall ecological assessment, mapping and analysis (Miller 1980).
6. **Research and monitoring programmes.** Management can be effective only to the extent that it is supported by information and knowledge. A research and monitoring programme is an essential component of management and administration. Trends in plant succession, migratory patterns of birds and ungulates, and stream flow are but a few indicators of change that may show positive or negative responses to human interventions (see, for example, Kraus and Brown 1992; Bourdages *et al.* 1992). In addition, countries may wish to link protected-area research programmes to the inventorying of the areas' biota, systematic screening, and chemical prospecting with an eye to potential biotechnological applications (Reid *et al.* 1993).
7. **Biological-resource management programmes.** A biological-resource management plan can clarify possible needs for interventions (fire, restoration, eradication of exotics, captive breeding, etc.), and their geographic placement, seasonal timing, etc. The plan should also include prescriptions for the protection of key genetic resources, for fostering or maintaining patch dynamics, and for other detailed measures. As discussed in subsequent sections of 13.4, an array of methods is available for conserving biodiversity at the genetic, species and habitat/ ecosystem/landscape levels. In an ideal protected areas context, these methods are applied as called for in the management plan as a result of findings from the research and monitoring programme (see 6 above).
8. **Education programmes.** Protected areas are excellent places for educating people about nature and the relationship between nature and people. Examples from all over the world demonstrate a variety of effective approaches to education through interpretative materials, exhibits, and opportunities for viewing wildlife and plants. Various countries (e.g. Costa Rica: Gámez 1993) consider the intellectual development of their people to be one of the primary goals of their protected area system.
9. **Use management programmes.** All IUCN management categories feature one or more types of human use, ranging from direct uses (tourism, recreation, education, research, monitoring, genetic resources, extraction of non-timber products, timber, wild game, fish, etc.) to indirect uses (environmental services, such as water, air, climate regulation, soil conservation and geochemical cycles). The degree to which biodiversity can be conserved at the genetic, species and landscape/ecosystem levels will depend on how these use regimes are managed (see 13.3 and subsequent sections of 13.4).
10. **Bioregional management programmes.** Protected areas are components of a larger landscape or seascape, as noted in 13.1. For biological, ecological, economic and socio-cultural reasons, protected areas cannot accomplish their objectives if they are treated as islands within regions of land- or water-use conflicts and impoverishment. Protected area management where biodiversity is a major objective will succeed only to the extent that co-operative arrangements are made among public agencies, local residents and industry. These agreements must ensure that the management of biological resources and ecosystems in adjacent areas are consistent with the management objectives of the protected areas.

Examples of advanced work on bioregional management include the tri-country Waddensee programme along coastal Denmark, Germany and the Netherlands (Wadden Sea Assessment Group and Trilateral Working Group 1991), the Serengeti Greater Ecosystem in Kenya and Tanzania (Ministry of Tourism, Natural Resources and Environment 1991), La Amistad in Costa Rica and Panama (Gobierno de Costa Rica 1990), the Great Barrier Reef in Australia (Murdoch 1992), and Yellowstone National Park in the United States (Rawlins 1994), as reported by Miller (1995).

13.4.2.1.4 Effectiveness of protected areas for maintaining biodiversity. Two issues are critical in assessing the effectiveness of protected area systems for biodiversity conservation. First, do the protected areas have clear biodiversity management objectives and the appropriate boundaries, legal status, funding and personnel to obtain those objectives? Second, do local people benefit economically from protected areas, and do they have incentives to use the resources in surrounding areas sustainably? Assessing the biological effectiveness of a protected area network requires information on the range of biodiversity elements contained within the area, and on the quantity and kind of management inputs going into protected areas management.

While reasonably accurate data on the number and area coverage of protected areas are available for most countries, more specific information on the effectiveness of protected areas in conserving elements of biodiversity is generally not available, even for countries with well-established protected areas. For example, Newmark (1987) documented the extirpation of large mammals during the twentieth century in every national park in the continental United States, indicating the lack of systematic monitoring and protection even of large mammals in the US National Park System. While some countries have attempted to conduct surveys of key species, information on the biodiversity contained within protected areas is inadequate for virtually all groups, except some vertebrates. Monitoring of genetic diversity has received far less attention than it deserves.

In India, which has a protected areas network of over 500 national parks and nature reserves covering nearly 5% of the country's land area, two nationwide surveys have been conducted to assess the effectiveness of the network. On the biological front, the Wildlife Institute of India evaluated the biogeographic coverage of the existing protected areas network and suggested options to plug the major gaps (Rodgers and Panwar 1988). The second survey (Kothari *et al.* 1989), conducted simultaneously by the Indian Institute of Public Administration (IIPA), looked at various management parameters of the protected area

network: legal status, research and monitoring, human use and management activities (see Box 13.4-2).

McNeely *et al.* (1994) review protected areas management effectiveness around the world. Priority actions to improve management and increase the ability of protected areas to conserve biodiversity are presented by region (14 regions including coastal marine areas).

Social and economic measures to enhance the compatibility of biodiversity management in protected areas with economic and social development are presented in 13.5. These measures are vital to the success of protected areas management strategies in developing countries, and frequently in developed countries as well.

13.4.2.2 Managing corridors and natural habitat fragments

Fragmentation of natural ecosystems is generally seen to be one of the most important threats to biodiversity worldwide (Saunders *et al.* 1991; Bierregaard *et al.* 1992; Kattan *et al.* 1994). Fragmentation occurs when human activities such as agricultural development, forestry or urbanization remove large proportions of the natural ecosystem and replace them with a greatly modified matrix, within which small remnants of the native ecosystem remain. This process results not only in vastly reduced areas of the natural ecosystems but also their subdivision into small and relatively isolated fragments. Roads, railroads, powerlines and pipelines are also important fragmentation factors in many places, although they may not directly convert large areas of habitat.

13.4.2.2.1 Response of ecosystems to fragmentation. The response of biota to ecosystem fragmentation has received much study and is well documented in the conservation literature. This research has largely centred on species and community responses to changes in ecosystem size and isolation, most of it within the theoretical framework of island biogeography (Diamond 1975; Wilson and Willis 1975; Simberloff 1988; Shafer 1990; Soulé 1991). Considerable debate has focused on such questions as whether a small number of large reserves will maintain native biota better than a larger number of smaller reserves, and whether reserves linked by corridors are better than those without linkages. Much of this debate has been carried on with a paucity of data from real systems. Saunders *et al.* (1991) pointed out that, until recently, relatively little emphasis has been placed on understanding the effects of fragmentation on the structural and functional aspects of natural and managed ecosystems.

Much attention has been focused on the effects of habitat size and isolation on the biota in remnant areas. It was suggested that remnant areas should be similar to islands and that the biota should follow the rules developed by island biogeography (Diamond 1975; Wilson and Willis 1975). While the biogeographic processes operating as a

Box 13.4-2: Biological and management effectiveness in India's protected areas system.

A review of India's protected areas system (Kothari *et al.* 1989) demonstrated that:

1. The process of selecting protected areas and determining which protection category to put them in was arbitrary, unsystematic and inconsistent. Protected areas were also not placed in any rational system of regional land-use planning. As a result, highly degraded or densely settled areas were designated as national parks (the highest form of protection under Indian law), and important biodiversity areas were not included in the network.
2. As many as 60% of the national parks and 92% of the sanctuaries had not completed the required legal procedures for their establishment as protected areas. Lack of co-ordination between the Forest Department wildlife authorities and the civil administration responsible for land acquisition was partially responsible.
3. Management planning was widely classified as seriously deficient – only 43% of the national parks and 28% of the sanctuaries reported the existence of management plans. No detailed guidelines for preparing plans exist, and available plans were often assessed as inadequate.
4. Research was reported in only 42% of national parks and 23% of sanctuaries, with even fewer reporting the existence of basic research facilities. Regular monitoring was absent virtually everywhere, with the exception of a periodic census of large mammals and birds in some areas.
5. Funds for staff and equipment were highly deficient, compromising efforts to protect and manage these areas (only 1.5% of Forest Department budgets went to protected areas management in 1984, and there are few indications that this has increased during the past decade).

These management deficiencies weaken the ability of India's protected areas network to conserve a representative range of the country's biodiversity. The IIPA report made a number of recommendations to improve the situation, some of which are under consideration by the central and state governments. IIPA is now following up with detailed assessments at the level of each state and union territory, with comprehensive directories of protected areas being one result (Singh *et al.* 1990; Pande *et al.* 1991; Lal *et al.* 1994).

result of habitat reduction and isolation undoubtedly have a profound impact on the biota of fragmented systems, the alteration in landscape processes resulting from fragmentation also has large impacts.

Most studies of fragmented systems concentrate on the fragments, and most conservation management is conducted within individual fragments. However, fragments of native vegetation sometimes make up only a small percentage of the landscape and are heavily influenced by the surrounding matrix of agricultural (or other production-based) land. The switch from continuous cover of native vegetation to small fragments in a predominantly altered matrix brings with it many important consequences for remnant vegetation, over and above the biogeographic effects of reduced area and increased isolation (Saunders *et al.* 1991; Hobbs 1993). These stem from changes in physical, chemical and biotic flows in the altered landscape. The consequences are particularly important at fragment edges, where significant changes in microclimate and vegetation can occur, with concomitant effects on the native fauna (Kapos 1989; Laurance *et al.*

1993; Matlack 1993a,b; Scougall *et al.* 1993; Sisk and Margules 1993; Laurance 1994). Also relevant are changes in the disturbance regime and the spread of disturbance through the fragmented landscape (Hobbs 1987; Baker 1992), with resulting changes in ecosystem dynamics (e.g. Yates *et al.* 1994).

An important alteration to regional hydrology can result from the extensive fragmentation of native vegetation. For instance, in the Western Australian wheat-belt, removal of native vegetation and its replacement with annual crops and pastures results in considerably less efficient use of rainfall, increased runoff and greater inputs to the water table (Nulsen *et al.* 1986; McFarlane *et al.* 1992, 1993). This has led to rising water tables – raised by as much as 50 centimetres per year in some areas (George *et al.* 1995).

Beneath much of the wheat-belt are considerable quantities of salt stored at depth. As water tables rise, the stored salt is mobilized, and wherever the water table reaches the surface, salinization occurs. Salinization and waterlogging have resulted in the loss of large areas of productive farmland (McFarlane *et al.* 1993) and also

threaten the fragments of native vegetation. Many low-lying areas are affected, and most of the lakes have now gone saline (Froend *et al.* 1987; Froend and McComb 1991; Hobbs *et al.* 1993). In some areas the water table is rising so quickly that remnant vegetation will be destroyed within the next 5–10 years (George *et al.* 1995). Such considerations are also relevant in many other areas. The importance of surrounding land uses in altering the hydrological balance, and hence compromising the conservation values of reserve areas, is being increasingly recognized (Rowell 1986; Green and Robins 1993; Harding 1993).

As well as physical and chemical flows in the landscape, the flow of biota from the surrounding matrix can threaten the integrity of fragmented ecosystems. This can include grazing by domestic stock (Scougall *et al.* 1993), the influx of feral herbivores, predators, and non-native plant species (Kinnear *et al.* 1988; Friend 1990; Brothers and Spingarn 1992; Hester and Hobbs 1992), and increased predation rates, especially at fragment edges (Brittingham and Temple 1983; Martin 1988; Small and Hunter 1988; Paton 1994). Insect communities are also strongly affected: for example, native pollinators are often displaced by wild or hive-based honey bees. These factors often pose the greatest threats to biodiversity in fragmented systems.

The above discussion illustrates that ecosystem fragmentation does not entail a simple reduction in area and increase in isolation. Accompanying these changes are many other impacts. It may be very difficult to understand these dynamics since we cannot differentiate between the effects of fragmentation *per se* and the effects of matrix-derived influences. The difficulty of interpreting *post hoc* what is happening in fragmented systems is also highlighted by recent studies in Mexico, where studies of recently fragmented forest areas have shown that regeneration dynamics and vegetation structure are markedly altered, not by fragmentation *per se* but by the loss of large herbivores (Dirzo and Miranda 1990; Dirzo 1992).

Without some knowledge of the dynamics of the unfragmented system, such insights would have been impossible. This therefore suggests that we should be cautious in our attempts to understand long-fragmented systems. What we observe may make little sense simply because the dynamics are now far removed from those prevailing in the original system. This also influences the way in which we should go about managing these systems.

13.4.2.2.2 Corridors in fragmented landscapes. Biotic movement in a fragmented landscape requires movements among individual fragments. Many fragments are likely to be too small to support populations of many native animal species, and hence these need to move around the landscape to fulfil their resource and habitat requirements. Corridors of native vegetation linking fragments are commonly seen as a solution.

Much debate has centred on the utility of corridors, following the initial enunciation of their value in terms of biogeographic design (Noss 1987; Simberloff and Cox 1987; Harris and Scheck 1991; Hobbs 1992; Simberloff *et al.* 1992). Faunal studies have indicated that considerable movement between remnants does occur, at least for some species (Saunders and de Rebeira 1991; Arnold *et al.* 1993). Corridors are likely to enhance the probability of movement and survival, even if they are not essential for this. Hobbs (1992) suggested that unequivocal data on the requirement of corridors for movement would be very difficult to obtain. Recent radiotelemetry studies by Lynch *et al.* (1995) have indicated that the biotic movement function that corridors provide may actually be secondary to an important habitat function. Corridors thus act as additional habitat and as representatives of the native ecosystems in their own right.

Corridors are, therefore, often an important component of the conservation network. They are, however, more prone than are remnant areas to the many external (i.e. matrix-derived) influences discussed above, since their long, narrow shape leads to a high edge-to-area ratio. They are also more susceptible than the equivalent remnant areas to nutrient enrichment, weed invasion and episodic insect attack (Cale and Hobbs 1991; Hobbs and Atkins 1991; van Schagen *et al.* 1992). Corridors thus require more costly and intensive management than do larger blocks. It has also been suggested that corridors may act as conduits for disease and pest species (Pysek and Prach 1993; Hess 1994; Inglis *et al.* 1994). Depending on corridor characteristics, they may be used only by cosmopolitan species. In a review of scientific evidence, Dawson (1994) found that corridors:

- sometimes allow individual animals to survive by giving them access to sufficient habitat to meet their needs;
- can maintain populations of some animal and plant species by replenishment; however, most probably either fail to use a corridor (perhaps because it is not wide enough) or can cross gaps between patches of habitat without corridors; and
- can serve the needs of some migratory animals in their seasonal movements.

For corridors to be effective for species restricted to the interior of fragments, they need to be wide enough to contain a significant area of interior (or 'non-edge') environment. The present limited knowledge suggests that corridors should be used where they can be cost-effective, since they do permit some species to thrive where they otherwise would not, and the habitat type chosen or created for corridors should match the requirements of the target species (Dawson 1994). Corridors will be most effective

when they protect the known movement routes of migratory or highly mobile species. The decision to include corridors in a conservation network has therefore to be taken with these factors in mind. Simply establishing corridors between existing fragments or parks, without demonstrable need or plan, may not be the best use of limited funding.

13.4.2.2.3 *Protection and management of fragments.*

The protection and management of natural habitat fragments requires a reduction in the deleterious effects of matrix-derived influences on remnants and an increase in the area and connectivity of habitat. Where fragmentation is ongoing, this can be achieved by ensuring that the remaining native vegetation is arranged optimally, as far as we can determine with current knowledge. This means that representative areas of all major ecosystems in a region need to be reserved, that blocks should be as large as possible, that buffer zones should be established around core areas, and that corridors should connect these areas. This basic design is central to the recently proposed Wildlands Project in the United States (Noss 1992), a controversial long-term strategy (100 or 200 years) to expand natural habitats and corridors to cover as much as 30% of the US land area. While the basic recipe appears simple and perhaps over-ambitious, the actual selection of core areas and of priority areas for reservation can be problematic, and must be linked to clear conservation objectives. A variety of reserve selection procedures is available (e.g. Usher 1986; Margules *et al.* 1991; Pressey *et al.* 1994; see also 13.2).

Frequently, however, conservation considerations do not play an adequate part in determining the patterns of fragmentation and many areas are already extensively fragmented. In these cases, retroactive action that involves the protection of existing fragments and the enhancement of the existing network is required. Protection must deal adequately with the threats from the external matrix, and thus includes fencing against stock, prevention of weed invasion, and prevention of degradation by human populations. Many of the external threats cannot be dealt with adequately by on-site management alone – management of the surrounding landscape will also be needed. This is a distinct departure from traditional conservation management that has focused almost entirely within individual remnant/reserve areas and has been conducted by conservation agencies largely in isolation from or in opposition to surrounding land managers (see 13.1 for discussion of bioregional management).

A broader perspective is needed that encompasses the entire landscape, including the conservation and production components (Hobbs and Saunders 1991; Hobbs *et al.* 1993). It also requires increased co-operation between neighbouring landowners and managers. Conservation

agencies that have often ignored the human community surrounding nature reserves are now becoming dependent on the co-operation and goodwill of that community to ensure that reserves and the non-reserved habitat remnants continue to form an integral part of the conservation network (see 13.5 for assessment of participatory planning and management; see 13.7 for building capacity to carry out integrated biodiversity management and sustainable use activities).

13.4.2.3 *Maintaining ecosystem functions and processes*

A variety of tools may be needed to maintain or mimic disturbance regimes, such as fires, grazing, treefalls or flooding, that are key elements in the persistence of certain species and habitat types. For example, when land is set aside as a protected area, the pattern of disturbance and human use may change so markedly that many species previously found on the site disappear (Gómez-Pompa and Kaus 1992). Alternatively, a newly constructed dam may substantially alter or eliminate flooding cycles that certain species or habitat types depend on for their survival (Holloway 1994). ‘Keystone’ resources, such as standing dead trees or mineral salt licks, that have been lost or are insufficient to sustain a viable population of a rare species in a small area, may need to be enhanced (Primack 1995). The protection, restoration and enhancement of ecosystem processes and functions are vital components in many conservation strategies.

The importance of fire in maintaining healthy ecosystems, wildlife populations and biodiversity has been widely recognized in recent decades. Fire, a common natural disturbance event in some ecosystems, has been suppressed in many areas. As a result, early successional habitats and their associated species, that were once common, have become rare or absent. For example, some of the unique flowers found on the island of Nantucket off the Massachusetts coast are found in coastal heathland areas previously maintained by sheep grazing, and infrequent fires have become rare as scrub oak forest has encroached and shaded out the flowers with the disappearance of both sheep and fire (Primack 1995).

In response, land managers have increasingly used ‘prescribed fires’ to improve wildlife habitat and recover endangered species. For example, The Nature Conservancy (TNC) conducted its first prescribed burn in a North Dakota mixed-grass prairie habitat in the early 1970s to stimulate the regeneration of several rare plants dependent on fire for regeneration (McLean 1995). Today, TNC conducts burns on nearly 20 000 hectares of grassland and forest habitat around the United States. The organization’s fire specialists work with ecologists to carefully document the ecological effects of fire. Several hundred thousand hectares of forest and rangeland are burned on US National Forests each year, often for wildlife and biodiversity

conservation objectives. Prescribed fires, however, can be risky and generate public opposition when they go out of control (McLean 1995). The effects of fire on the composition, function and structure of a variety of ecosystems are documented in Pickett and White (1985). Falk (1992) describes other strategies for maintaining early and mid-successional plant communities that have been suppressed by changes in disturbance regimes.

The diversity of wetland ecosystems is particularly affected by changes in hydrological regimes (Moyle and Leidy 1992). Water levels and the periodicity of low and high water are vital to the survival of many species. Irrigation projects, dams, drainage canals and flood control levees frequently have dramatic impacts on the diversity and abundance of riparian and wetland species. In Florida's Everglades, decades of canal and levee construction have brought in too much water for many species when it is not needed and too little water when it is. Dozens of species found only in the Everglades are at risk of extinction due to these changes while many tropical plants intentionally or accidentally introduced from elsewhere thrive in the new environment (Holloway 1994). In Kashmir, Pandit (1991) documents a long list of plants, fish and birds that have declined during the past 40 years as drainage ditches, filling of wetlands, and increased flooding due to changes in land cover have become more common.

In response, wildlife managers are manipulating water levels to favour the growth of food plants, constructing sediment traps to maintain water quality, banning draining, filling, and burning in sensitive areas and planting vegetative cover on slopes bordering wetlands (see, for example, Pandit 1991; Holloway 1994). Geologists are seeking to reconstruct past flooding regimes on rivers in the western United States where they no longer exist because of impoundments. The absence of these flooding regimes has significantly altered riparian ecosystems. With information on natural flooding regimes along the Platte River in Nebraska, wildlife managers hope to change the timing of water releases on upstream dams to recreate the disappearing sandbar habitats that sandhill cranes depend on during their annual migrations.

Much of the work on protecting and managing ecosystem processes to conserve biodiversity has been carried out in the growing field of restoration ecology. The distinction between managing existing communities and establishing new ones is recognized by Falk (1992):

In the past, successional species generally had somewhere to migrate to; local extirpations were probably relatively common, but there were always new populations emerging. Now that the few parcels of undisturbed land are increasingly fragmented, it will become necessary to restore migratory pathways and to use site management to ensure that adequate successional diversity is maintained.

See 13.4.4 for discussion of ecosystem restoration and rehabilitation.

13.4.3 Protecting species, populations and genetic resources

The most effective and efficient way of conserving biodiversity, by almost any reckoning, is to prevent the conversion or degradation of habitat to begin with. There is no alternative for conserving the diversity of landscapes and ecosystems. But these measures must be complemented by a wide array of techniques to conserve individual species, populations and genes. The options range from species-management programmes in the wild (*in situ*) to off-site (*ex situ*) protection in botanical gardens, zoos, gene banks and aquaria. As discussed in 13.1, an integrated approach to conservation – one that makes use of this entire range of measures – is a cornerstone of biodiversity conservation.

During the past 500 years, extinction rates have increased rapidly (see Section 4) and human actions during this time have been comparable to past geological cataclysms in terms of habitat disruption and species extinction. Highly endangered high-profile vertebrate species, such as black rhinoceros (*Diceros bicornis*), receive most of the media coverage, but may be far less important to humans and the environment than the vastly more numerous but less noticeable invertebrate, plant, fungus, and single-celled species that are being wiped out in obscurity.

Beyond species loss, the erosion of genetic variation is even less obvious and probably much more severe. For example, Lleras *et al.* (1992) have shown that while human-induced species extinction in the Amazon Basin has not been extensive to date, humans have contributed to substantial loss of genetic variability in many species important to humans in the ecotone between the Amazon and the Cerrado.

It is increasingly obvious that conservation is, intrinsically, about the whole array of biodiversity elements, from the tropical forest and all other major ecosystems and 'charismatic megavertebrates' to the vast diversity of plant, invertebrate and microbial species, some of which are undoubtedly keystone species that maintain the diversity and productivity of natural and human-dominated ecosystems. The marginal interest of breeders in ecosystems, communities, species and even populations, and the conservation biologists' lack of interest in genetic resources have hobbled the effectiveness of past conservation efforts. This has been exacerbated by the overall shortage of conservation funding that pits funding for rain forest protection against agricultural diversity conservation (Esquinas-Alcazar 1993).

Today there is a growing awareness that all levels of biodiversity form part of a whole and are interdependent (FAO 1989). This has been well emphasized by the Convention on Biological Diversity signed during the 1992 UN Conference on Environment and Development (UNCED) held in Rio de Janeiro. Genetic resources have

finally, and deservedly, been recognized as priorities for conservation within diverse ecosystems (UNEP 1992).

13.4.3.1 *Threatened and endangered species classifications and species management and recovery plans*

13.4.3.1.1 *Threatened and endangered species classifications.* When the IUCN established the Species Survival Commission (SSC) nearly 30 years ago, it established several categories of threat by which to classify species by their potential risk of extinction. Species meeting the criteria for inclusion in one of the categories are then included in *Red Lists* and *Red Data Books* (e.g. IUCN 1990). A growing number of countries have also adopted the traditional *Red Data Book* approach (WCMC 1994). The purpose of these compilations is to develop a database of threatened species, provide the basis for setting species conservation priorities, and monitor the effectiveness of recovery efforts.

Until 1994 when a new categorization was approved, six categories were used, with some modification, to highlight threatened species (Mace and Stuart 1994). These categories were: Extinct, Endangered, Vulnerable, Rare, Indeterminate and Insufficiently Known. The general term 'threatened' has been used to refer to a species belonging to any one of these categories. Useful as the system was for drawing attention to species conservation, many scientists criticized it for being over-subjective. For example, 'Endangered' was defined as, 'Taxa in danger of extinction and whose survival is unlikely if the causal factors continue to operate. Included are taxa whose numbers have been reduced to a critical level or whose habitats have been so drastically reduced that they are deemed to be in immediate danger of extinction.' Categorizations made by different authorities varied and did not always accurately reflect real extinction risks (WCMC 1992).

In 1987, the SSC Steering Committee began an effort to revise the threatened species categories. The goal of the revision was to introduce more objective methodology and criteria, based on population viability analysis, to assign species to threatened categories. After seven years and at least four versions (Mace and Lande 1991; Mace *et al.* 1992; IUCN 1993a; Mace and Stuart 1994), the new threatened species categories were finally completed and approved at the 1994 CITES conference.

The new system (IUCN 1994; see Box 13.4-3) has ten categories: Extinct, Extinct in the Wild, Critically Endangered, Endangered, Vulnerable, Conservation Dependent, Near Threatened, Least Concern, Data Deficient and Not Evaluated. Detailed criteria were established for three of the categories: Critically Endangered, Endangered and Vulnerable. Each category uses the same five criteria: (i) population and habitat decline, (ii) habitat area, (iii) population fragmentation or isolation, (iv) population size, and (v) population viability analysis. Different quantitative

thresholds are used for each category. For example, the mature population size criterion for Critically Endangered is fewer than 50 mature individuals, while the threshold is 250 for Endangered and 1000 for Vulnerable. To be included in a category, a species needs to meet only one of the five criteria (Mace and Stuart 1994). The criteria and the quantitative threshold values for criteria in each category were determined through wide consultation.

Mace and Stuart (1994) applied the new system to eight species to illustrate how the system would work. Critiques directed at earlier versions questioned whether the proposed system would be practical to use for species not well known and for which relatively little quantitative information exists. They concluded that the criteria do not require large amounts of quantitative data before they can be applied. However, since most of the species tested are actively involved in international trade (and thus monitored by CITES), these examples are probably not representative of most species.

Ironically, the new system has received criticism for being too quantitative. For example, the US delegation to the 1994 CITES conference criticized the numerical rankings as being too specific for the vast majority of rare and potentially threatened species, leading to possibly serious errors. In addition, the costs of quantitatively determining species status could result in many countries, particularly developing countries, being unable to protect their wild flora and fauna from excessive international trade (Jones 1994). Its proponents (e.g. Mace and Stuart 1994) have stressed the ability to make a determination of Critically Endangered, Endangered or Vulnerable on the basis of meeting any one of the five criteria. Guidelines for the use of the system have been prepared and Mace and Stuart (1994) urge users to read all sections of the document carefully and to understand the guidelines before applying the new categories.

Regardless of whether a species was classified as threatened under the old or the new system, it must be stressed that Red Lists are compendia of species known to be threatened. Many more species will in fact be threatened but not listed because little information exists or because they have not yet been categorized. For example, while all known bird species have been reviewed, only 50% of the world's mammals, less than 20% of reptiles, 10% of amphibians, and 5% of its fish have been reviewed for potential threatened classification (WCMC 1992).

While it is too early to conclude how effective the new system is, the use of more objective, scientifically based criteria is an important step in threatened species classification. IUCN and others (see BSP *et al.* 1995) are working to develop similar methods of landscape classification for threatened habitat categories (Stuart and Sullivan 1994).

13.4.3.1.2 *Management plans.* Many species are subject to management plans at both national and international

Box 13.4-3: The revised IUCN Red List categories (from: IUCN 1994d).

Red List Category	Definition
Extinct	There is no reasonable doubt that the last individual of the taxon has died.
Extinct in the Wild	The taxon is known only to survive in cultivation, in captivity or as naturalized population (or populations) well outside the past range. A taxon is presumed extinct in the wild when exhaustive surveys in known and/or expected habitat, at appropriate times (diurnal, seasonal, annual) throughout its historic range have failed to record an individual. Surveys should be over a time frame appropriate to the taxon’s life cycle and life form.
Critically Endangered	The taxon is facing extremely high risk of extinction in the wild in the immediate future.
Endangered	The taxon is not Critically Endangered but is facing a very high risk of extinction in the wild in the near future.
Vulnerable	The taxon is not Critically Endangered or Endangered but is facing a high risk of extinction in the wild in the medium-term future.
Conservation Dependent	The taxon is not Critically Endangered, Endangered or Vulnerable but is the focus of a continuing taxon-specific or habitat-specific conservation programme targeted towards the taxon in question, the cessation of which would result in the taxon qualifying for one of the threatened categories above within a period of five years.
Near Threatened	The taxon is not Critically Endangered, Endangered, Vulnerable or Conservation Dependant but is close to qualifying for Vulnerable.
Least Concern	The taxon is not Critically Endangered, Endangered or Vulnerable and does not qualify for Conservation Dependent or Near Threatened.
Data Deficient	There is inadequate information to make a direct, or indirect, assessment of the risk of extinction based on the distribution and/or population status of the taxon. A taxon in this category may be well studied, and its biology well known, but appropriate data on abundance and/or distribution are lacking. Listing in this category indicates that more information is required and acknowledges the possibility that future research will show that threatened classification is appropriate.
Not Evaluated	The taxon has not yet been assessed against the criteria.

levels. At the national level, legislation has been enacted in many countries to provide a legal basis for sustainably managing or protecting species (see also 13.6.3.1). Management plans are usually introduced either because the species in question is perceived to be under some sort of threat (e.g. ‘endangered’), or because it is economically valuable. In many cases, such as the European Birds Directive or species recovery plans under the US Endangered Species Act, species management plans do not manage a species directly but work through habitat conservation activities to conserve a species.

Many management plans have failed, in large part because there is a confusion of objectives: namely, the contradiction between conserving the resource and maximizing the short-term economic benefits to user groups. Some management plans, for example many fisheries management plans, have been more concerned with maintaining access to the resource for particular user groups or industrial sectors than with protecting sustainability of the species or the resource (see 13.3.4). Species management plans at the global level have most frequently been adopted for marine fisheries. In most cases,

vested economic interests have prevented such stocks from being managed sustainably, at least until such time as the stock is severely threatened with economic extinction (Ludwig *et al.* 1993). The collapse of the Western Atlantic cod stocks and conflicts between Canada and the European Union over fishing on the Georges Bank are examples. Occasionally the opposite occurs, when a well-protected species recovers enough to allow limited harvesting. For example, the Revised Management Procedure (RMP) for whales – a plan to selectively lift the international moratorium on whaling – adopts a precautionary approach to the harvesting of several species of whales. Strong public antipathy to whaling, however, has so far obstructed the adoption of the RMP, which is based on years of scientific research.

The possibility exists of developing species management plans within the context of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). Management plans under CITES have generally involved either export quotas or ranching programmes, designed to ensure the sustainability of uses of the species concerned. These show promise if they are biologically robust as well as economically viable (see also 13.3.5).

13.4.3.1.3 Recovery plans. Recovery plans are a special kind of species management plan, usually developed under legislation designating special status for threatened and endangered species. For example, the US Fish and Wildlife Service is required to develop a recovery plan for any species formally listed as an endangered species. The basic format of species recovery plans is similar the world over. The introduction includes information on the species' ecology and the reasons for its decline. The goal of the plan is then stated, which is usually to achieve enough recovery to allow down-listing of the species to some non-threatened category. Most plans usually include a list of proposed measures – sometimes a long and exhaustive list – to bring about the recovery of the species in question. Such measures most often include establishing protected areas or other forms of habitat conservation, but may also include captive breeding, reintroduction to natural habitats, restriction of harvesting, and reduction of levels of toxic materials in the environment. The final part is usually an implementation schedule, often with a budget. Recovery plans often have the advantage of stimulating co-operation – or at least the prompt exchange of information – between those who have, or who should have, responsibilities for reversing a species' decline.

In reality, many species languish for years on threatened and endangered species lists without a recovery plan. Administrative requirements, gathering scientific information, consultation with NGOs and the public, and limited funding, all contribute to a long gestation period for the typical recovery plan. The plans also often fail to involve local people who are affected by measures to

protect species, a weakness that limits the effectiveness of implementation and may breed resentment against legislation and policies to protect endangered species. Education programmes, which often constitute the public component of a recovery plan, are no substitute for the involvement of local people in the development of the plan itself. Conservation agencies are now beginning to recognize the importance of involving local stakeholders in the development of such plans, an important step relevant to the development of endangered species recovery plans around the world (see 13.5 for participatory mechanisms).

From a technical point of view, effective recovery plans depend on several factors (Caughley 1994):

1. Recovery plans must accurately diagnose the factors causing a species' decline. In many plans, the factors driving declines are assumed, but are not unequivocally demonstrated. Invalid assumptions can, of course, lead to inappropriate recovery strategies that leave the species in an unimproved or even worse condition, perhaps at the loss of significant time and money.
2. Recovery plans should examine the feasibility of recovery options rather than simply list an undifferentiated universe of possible actions.
3. Recovery plans should be implemented using adaptive management techniques so that the successes and failures of the plan can be determined and used to revise both the implementation of the existing plan and the design of future recovery plans. This means that measurable criteria need to be defined in the plan and monitored during implementation in order to assess progress. To avoid the danger of species recovery plans becoming an end in themselves rather than a tool for improving the conservation status of endangered species, Caughley (1994) suggests planners ask seven basic questions:

- What do we want to achieve?
- Can we get there?
- Will we know when we get there?
- How do we get there?
- What are the costs associated with getting there?
- What benefits are to be gained by getting there?
- Will the benefits exceed the costs?

13.4.3.1.4 IUCN Species Survival Commission Action Plans. Some recovery plans operate at a scale different from that of national species recovery plans. In the mid-1960s, the International Union for the Conservation of Nature (IUCN) established the Species Survival Commission (SSC) to focus expert attention on the status and conservation needs of distinct groupings of wild species. The SSC, with over 5000 members in 167 countries, is the largest of the six voluntary commissions of

the IUCN. There are now 102 Specialist Groups covering mammals, birds, invertebrates, reptiles, fish and, to a lesser degree, plants. Each of these Specialist Groups is a volunteer network of scientists that seeks to generate and update information on the species covered by the group, and to devise and implement programmes to conserve the most threatened of those species in collaboration with IUCN members. The most important responsibility of the Specialist Groups is to develop an Action Plan that provides a comprehensive overview of all the species within their group, establishes or applies a system for setting research and conservation priorities, and proposes projects to address those priorities (Stuart 1987).

Since 1986, the SSC has published 24 plans on mammals, two on reptiles, and one on insects. Another 43 plans are currently being written by Specialist Groups: 21 on mammals, 7 on birds, 3 on reptiles and amphibians, 3 on fish, 3 on invertebrates, and 7 on plants. Not surprisingly, the Action Plans use various priority-ranking schemes reflecting differences in data quantity and quality, the number of species covered by the Specialist Group, and other factors perhaps best known to members of the particular group (see Johnson 1995). The Action Plans typically rank conservation priorities for several objectives such as research needs, habitat protection, captive breeding and reintroduction.

But the Action Plans also have limitations. Since the conservation priority-rating systems vary from one animal or plant group to the next, it is not possible to rank conservation needs across groups. It is also often impossible to determine whether high-priority rankings for protected areas management, for example, are more important than an equivalent ranking for surveys or captive breeding. In many regions, the geographical conservation priorities of one Action Plan have not been correlated with overlapping priority areas identified in other Action Plans. However, as more Actions Plans are completed, IUCN is working to prepare regional and country overviews of priorities identified by various Specialist Groups. The first of these overviews (Stuart *et al.* 1990) includes countries in sub-Saharan Africa. Finally, there is the danger of obscuring elements of subjectivity behind the impression of numerical precision. However, as Cumming *et al.* (1990) point out,

The purposes of calculating and using such indices is to produce rational, dispassionate thinking into the process of setting priorities and to reduce arbitrary, subjective elements as much as possible. A primary function of such exercises is to make the rationale for choices explicit and so aid in reaching consensus about priorities for conservation action.

It should be recognized that SSC Action Plans are different from national species-recovery plans. They do not

attempt to be the last word on prescribing the recovery of a particular species. Rather, they attempt to identify global priorities for species conservation, and to make an initial assessment of the actions that need to be carried out, usually at national level. SSC Action Plans are, in a sense, precursors to national species recovery plans. The audiences for the SSC Action Plans are the government agencies and non-governmental organizations that are in a position to bring about their implementation.

The SSC is introducing new concepts into its action planning programme. For some Action Plans, especially those that involve large numbers of species, a workshop format has been introduced to carry out a rapid assessment of the global status of as many species as possible. These Conservation Assessment and Management Planning (CAP) workshops have now been carried out for over 20 groups of species, and their use is likely to increase.

Another innovation likely to be used in the future is to develop species action plans at the national level based on the model of those already carried out for wider geographic ranges by the SSC. Such national species action plans would be important contributions to national biodiversity action plans and strategies developed by Parties to the Convention on Biological Diversity. To stimulate this national approach, the SSC, working in conjunction with IUCN's Commission on National Parks and Protected Areas (CNPPA) and the IUCN Biodiversity Programme, is starting to develop national biodiversity groups.

The Action Plans developed by the IUCN Species Survival Commission Specialist Groups can be an important reference for nearly anyone involved in setting conservation priorities or having species management responsibilities. The SSC Action Plans are largely focused on addressing a wide audience and catalysing conservation efforts along lines that are considered to be of high priority. At the downstream end, national species recovery plans are much more detailed in terms of specific actions and implementation schedules. In either case, it is clear that all plans must be extremely focused on achievable and well-defined objectives if they are to be successful.

13.4.3.2 *In situ conservation of species, populations and genetic resources*

In situ species conservation measures usually emphasize the protection and management of ecosystems and communities to avoid the loss of resident species. Kemp *et al.* (1993) point out that even when the objective is the conservation of a particular target species or population(s) thereof, this objective may require the protection or management of whole communities – at least until there is a better understanding of the complexities and interactions between ecosystems and target species or populations. For example, most species are part of complex food-web systems composed of many other species, some of which

(e.g. 'keystone species') may be essential to the survival of the target species. Since these relationships are so often poorly understood, habitat protection may be the only prudent course of action.

It is also important to manage species for genetic resources to ensure that they have the range of genetic variation needed to survive in a changing environment. This variation also has potential value to human economic activities, as described in earlier sections.

Although there is sometimes a convergence of basic methodology, ecosystem and genetic resource conservation often differ in objective and degree. A programme of ecosystem protection and management is mainly addressed at the level of biotic communities – species and their relationships – whereas a programme of genetic resource use and protection is geared toward managing genetic variation within and between populations (FAO 1989; Lleras 1991). While ecologists and genetic resource specialists are both interested in species conservation, their methods and strategies complement – but do not substitute for – each other.

For example, the maintenance of a species' genetic diversity can be accomplished only by the protection of large populations in several different areas, while the conservation of a species *per se* may be possible through the protection of a single sample of an ecosystem with a much smaller species-population size. When the objective is to maintain the genetic integrity of a species, a multiple population approach is necessary (Namkoong 1986), and population sizes may need to be in the order of ten times those needed simply to maintain the survival of the same species (Frankel and Soulé 1981; Frankel 1983). Frankel (1983) suggests that conservationists are faced with three options in deciding whether and how to conserve the genetic diversity of targeted species:

1. To provide the habitat area required for survival and continued adaptive evolution without active intervention. This alternative is probably impossible in most situations today and will be even more so in the future.
2. To accept extinction, or remove the species from the environment to collections, botanical and zoological gardens, or other reserves, when habitat area requirements cannot be satisfied.
3. To manage the population size and population structure of the threatened species, which is the principal objective of *in situ* conservation.

Although it was initially believed that *in situ* conservation of genetic resources could be a 'stand-alone' endeavour, carried out by agriculture- and forestry-orientated institutions, for example, it is now clear that *in situ* genetic resource conservation is most likely to be

successful when it is part of the overall framework of conservation efforts in a country or region.

Lleras (1991) recognizes four categories of *in situ* genetic resource conservation strategies:

1. **Little or no management.** This strategy relies on national parks and other protected areas – or unprotected areas with minimal human disturbance – to maintain the population sizes and structures necessary to protect genetic integrity in wild species or populations of wild relatives of crop plants. Recent evidence, however, indicates that humans exert great selection pressure even in 'pristine virgin forests' and other natural ecosystems where anthropogenic influences have been under-appreciated until recently (e.g. Sombroek 1966; Lathrap 1970; Denevan and Zucchi 1978; Taylor 1988; Balée 1989; Gómez-Pompa 1990; Lleras 1992). Therefore, this strategy may be nearly as 'artificial' as the more intensive strategies listed below. A major constraint to this strategy is the lack of information on most species (Frankel 1983; Kemp *et al.* 1993) and major uncertainties about how effective hands-off management can be for maintaining genetic diversity in systems that may already have been or are substantially influenced by human activities.
2. **Moderate management.** This strategy relies on protecting traditional forms of extractivism and animal harvesting to maintain habitat and human practices that have shaped species diversity and have – at least for some manipulated species – contributed to genetic diversity. Brazil's extractivist reserves, where rubber tappers are allowed to tap rubber trees, but most other economic activities (e.g. logging, agriculture, mining, etc.) are restricted, are an example of such management and are appealing to advocates of sustainable development (e.g. Fearnside 1989; Smith *et al.* 1992). Most examples that would fall within this category, however, were designed for economic and social benefits (see further discussion on these issues in 13.5), not the conservation of genetic diversity *per se*. The genetic conservation benefits of such strategies are poorly known, although some work is being conducted (Potter *et al.* 1993).
3. **Intermediate management.** Where biological resources have been extensively manipulated over long periods of time, continued human intervention may be required to maintain species and genetic diversity. In the 1950s, for example, scientists in Israel tried to protect natural populations of *Avena* from disappearing by preventing grazing. However, since a number of *Avena* species had coexisted with grazing pressures for several thousand years, their survival strategies and life-history traits had

come to reflect these pressures. The removal of grazing, as a result, almost led to their extinction. This case has become a textbook example of the dangers of over-protection when species that have coevolved with disturbances, including anthropogenic disturbance, suddenly lose those factors in their environment (Odum 1971).

4. **Intensive management.** This strategy is targeted at domesticated or semi-domesticated species. Since the diversity of domesticated or semi-domesticated species is largely the result of human breeding, the population structure needed to maintain animal varieties and landraces of crops can be maintained only through intensive human management (Manglesdorff 1966; Lleras and Coradin 1986; Hoyt 1988). Retaining this genetic diversity *in situ* requires several approaches (see also 13.3.2). One approach is to retain at least some traditional agricultural practices. A second strategy is to integrate more diverse cropping and breeding systems into modern agriculture. Finally, the conservation of natural and semi-natural habitats where wild relatives of crop species are known to exist is another strategy that should be pursued (see previous *in situ* categories above).

While the principles of *in situ* management for the protection of genetic resources are well known, relatively few areas are actually managed for these purposes (Heywood 1993). In the Garo Hills of India, gene sanctuaries for wild relatives of citrus crops have been established and similar reserves for fruit trees are managed in other parts of India, and in China and Russia. India has several orchid reserves, Ethiopia maintains conservation areas for wild coffee, and a reserve dedicated to the protection of wild chillies (*Capsicum annum*) is maintained on the Coronado National Forest in Arizona (USA). In Brazil, the National Centre for Research in Genetic Resources (CENARGEN) has established seven genetic reserves for a variety of economically important species. More reserves are planned, and CENARGEN is planning to establish seedling banks of perennials *in situ* (Lleras 1991).

It is unclear how many species should be managed in *in situ* programmes. While FAO has conducted a review of *in situ* conservation needs for wild relatives of crop species (FAO 1985), there is no comparable survey for other plant species of economic or scientific interest. No serious attempts have been made – even for wild relatives of crop species – to elevate *in situ* management of targeted species to a prominent place on the conservation or development agenda (Heywood 1993).

Even if they were more widely implemented, *in situ* programmes would not always be available or sufficient to maintain the diversity of species, populations and genetic resources. While *in situ* programmes are nearly always

preferable when there is a choice, *ex situ* technologies have become increasingly useful as an adjunct to on-site conservation and restoration efforts. They are also increasingly effective in their own right.

13.4.3.3 *Ex situ strategies*

For centuries, gardens, zoos and menageries have been repositories for valuable plants and animals. Although they were often created for the aesthetic pleasure of the rulers of kingdoms and countries that sponsored expeditions, frequently these gardens, zoos and menageries served a more practical purpose. They became centres for the propagation and acclimatization of collected plants and animals that could be valuable to humans in their new environment (Smith 1986). During the last 500 years, these collections have become increasingly important as botanical and zoological gardens in Europe and other parts of the world collected and propagated many species for a variety of uses.

As agricultural and other research institutions developed independent germplasm collections in the first half of the twentieth century, the role of botanical and zoological gardens in conservation was gradually restricted to species with little or no apparent economic value. However, botanical gardens, zoological parks and aquaria have filled an increasingly vital new role as many plant and animal species face an increasingly threatened and uncertain future in the wild.

13.4.3.3.1 Botanical gardens. World-wide, there are now over 1500 botanical gardens and arboreta (Heywood and Heywood 1991), and together they maintain the largest assemblage of plant species outside nature (see also 8.5). While no overall assessment of the diverse array has been conducted, a botanic gardens database developed for the Botanic Gardens Conservation Strategy (WWF/IUCN/BGCS 1989) provides some idea of the biodiversity assets they contain.

As many as 80 000 species (about one-quarter of the world's higher plants) are cultivated in botanical gardens, with individual gardens housing anything from a few hundred to many thousands of species (Heywood 1992a). For example, the Royal Botanic Gardens at Kew in the United Kingdom hold about 38 000 species (about 10% of which are threatened) – more than most countries have in the wild. Only Brazil and Colombia have more plant species on their territory than Kew has in its collection on about 125 hectares. Until recently, however, most collections were built up in response to the interests of individual staff members or patrons, and conservation objectives were rarely expressed in institutional policies.

In recent years, however, an increasing number of botanical gardens have included plant resource conservation as a fundamental part of their mission. Today, over 500 gardens report having conservation collections

and over 100 report having seed banks, tissue culture facilities, and other *ex situ* technologies (Heywood 1992a). Breeding programmes – similar to those used by captive breeding programmes at zoological gardens – are being developed. For example, botanical gardens in the past were content to rely on their own collections for breeding purposes. Today they often co-operate to form breeding pools composed of individuals or populations from various institutions. This is especially important for the many species that have been totally eradicated from the wild and are now found only in these collections (Smith 1986). In 1987, Botanic Gardens Conservation International was established to co-ordinate the conservation activities of botanical gardens around the world. A consortium of North American botanical gardens established the Center for Plant Conservation, now at the Missouri Botanical Garden to increase collaboration in order to protect endangered species of North American flora.

One of the most important roles botanical gardens can play is to participate in recovery programmes for endangered species and degraded ecosystems (see also 13.4.4). Re-stocking, reintroduction and restoration activities provide a critical link between *ex situ* and *in situ* efforts to sustainably use and protect biodiversity. This partnership, however, is not yet well developed. So far, only between 100 and 200 species have been involved in recovery and reintroduction programmes (Heywood 1992a). Botanic Gardens Conservation International has organized workshops to address this issue and has developed guidelines for the reintroduction of species that are rare, endangered or extinct in the wild (Wyse Jackson and Ackeroyd 1994). Some botanical gardens mount major collecting and research expeditions that expand knowledge of plant distributions and ecology, and discover new species. Finally, with as many as 150 million visitors annually (Primack 1995), botanical gardens play an important educational role as well.

13.4.3.3.2 Zoos and aquaria. The role of zoos and aquaria is equally important (see also 8.6). Currently there are approximately 700 000 individuals of 3000 species of mammals, birds, reptiles and amphibians in approximately 800 professionally managed zoos around the world (IUCN 1993b). As with botanical gardens, the conservation role of zoos has been growing. Many zoos now have captive breeding programmes for endangered species and some, such as the National Zoological Park in Washington, DC, actively participate in programmes to breed endangered species and reintroduce them into their natural habitats.

Populations of many rare and threatened species kept by zoos are too small to maintain their genetic diversity. For example, of the 274 species of threatened mammal species maintained world-wide in zoos, only 10% have self-sustaining populations large enough to maintain the genetic diversity needed before reintroduction programmes can

begin (WCMC 1992). In general, a breeding population of 250 individuals is needed to maintain 95% of a species' genetic diversity over 50 generations. Of the 62 species of mammals kept in zoos that are listed by IUCN as endangered or extinct in the wild, 52 are breeding but 14 of these exist only as very small populations in one or two zoos (Olney 1993).

Many major zoos, therefore, have made major investments in building facilities and developing technologies to establish breeding colonies of rare and endangered species. To support these efforts, the IUCN's Species Survival Commission Captive Breeding Specialist Group provides information to zoos on housing conditions, nutritional requirements, and captive breeding technologies and strategies. To help prevent further inbreeding and genetic depression, the International Species Inventory System maintains a central breeding database with information on 4200 kinds of animals at 395 zoological institutions in 39 countries (Primack 1995). There are now international stud books for 104 species of birds and mammals, 68 of which are threatened. To effectively enlarge the breeding population of a species that any single zoo has, there is close co-operation among many of the larger zoos around the world that share breeding stock, frozen sperm, captive breeding technologies, etc.

Aquaria are perhaps the least advanced in captive breeding efforts (see also 8.6). Currently, aquaria maintain approximately 5800 species of fish, most of them collected from the wild (Olney and Ellis 1991). Techniques first used by the tropical freshwater aquarium trade are now being used to propagate endangered freshwater fauna such as the desert pupfishes of the American Southwest and the African Rift Valley lakes. Breeding programmes for marine fishes and corals are at an early stage. Based on their extensive experience with the breeding of common captive species, such as the bottle-nosed dolphin, aquaria will also have a major role to play in the conservation of endangered cetaceans (Primack 1995).

Ex situ conservation of animals is expensive. For example, Leader-Williams (1990) estimates that the cost of maintaining African elephants and black rhinos is 50 times greater than maintaining the same number of individuals in East African national parks. Conway (1988) notes that under current conditions in zoos around the world, no more than 900 species can be maintained for any length of time, and far fewer in breeding programmes conserving long-term genetic viability. Zoos that do not simultaneously invest in habitat conservation, while raising large amounts of funding to develop new captive breeding technologies and facilities in habitat conservation, may do little to enhance the survival prospects of endangered species. For example, large investments have been made in captive breeding programmes (which have failed, thus far) for the critically endangered Sumatran rhinoceros. Rabinowitz

(1995) believes that this has diverted attention and resources from the *in situ* conservation of the Sumatran rhino in Sabah, where two important populations of this species might still survive. Similarly, MacKinnon and MacKinnon (1991) fear that captive breeding programmes are ignoring the fundamental causes of species endangerment and thereby limiting the potential effectiveness of reintroduction programmes. They suggest that zoos ‘adopt’ protected areas and help raise funds for the protection and management of these sites in addition to developing captive breeding programmes. Others (e.g. Olney *et al.* 1994) believe resources spent on captive breeding would not necessarily be available for *in situ* conservation. With zoos attracting hundreds of millions of visitors annually, captive breeding programmes may be the closest many people come to learning about the challenges of conserving biodiversity.

13.4.3.3.3 Gene banks. The last decade has also seen the re-evaluation of genetic resource-conservation priorities for agricultural research institutions. In the past, these institutions were typically concerned only with the genetic resources of a few commercial crop and livestock species (see also 13.3.2). A variety of factors, including genetic vulnerability, the high environmental costs associated with the use of high-yield varieties, and limited or depleted soil and water resources, are stimulating these institutions to search for new uses for species utilized in the past and potential uses for some of the thousands of plant and animal species that are barely known to science.

Speculation that all useful species have already been domesticated (e.g. Hawkes 1969) is unlikely to stand the test of time. For example, a large number of potentially useful wild palm species are candidates for domestication (Lleras and Coradin 1986). Lleras *et al.* (1992) estimate that fewer than 50% of the plant species in the Amazon basin are known to science. The same may be true for other tropical ecosystems. Wild relatives of cultivated species of major potential in breeding programmes continue to be discovered.

Table 13.4-4 presents a synthesis of the plant and animal gene bank accessions that are conserved *ex situ*. For the major crops, a large amount of germplasm is available *ex situ*, and it represents a fairly high percentage of the cultivars known to exist (see Sections 2.2 and 3.1). The same is true for breeds of the major groups of domestic animals. Assuming these gene banks are effective in maintaining viable germplasm, it would appear that the genetic resources of the most important crop and animal species for human food consumption are not seriously endangered.

These data require careful interpretation, however, since many *ex situ* collections, particularly in developing countries, are poorly maintained or lack adequate storage facilities. While over 4.6 million accessions of plant

Table 13.4-4: Estimated accessions of domesticated plants (a) and animals (b) in *ex situ* gene banks.

(a) Plants		
Type of germplasm	Mean % landraces	Accessions
Cereals	79	2 082 621
Food legumes	68	743 756
Forage legumes and grasses	N/A	452 043
Vegetables	70	374 467
Fruits	N/A	243 823
Industrial crops	65	241 826
Roots and tubers	55	186 687
Oil crops	N/A	91 067
Sugar, beverage, spice crops	N/A	74 517
Others/unknown	N/A	117 253
Total plants		4 608 060
(b) Domestic animals		
Species	Breeds on File	Breeds at Risk
Ass	69	6
Buffalo	70	1
Cattle	845	120
Goat	330	39
Horse	360	99
Pig	368	69
Sheep	880	108
Total	2,922	442

(Adapted from Plucknett *et al.* (1987) and IPGRI (1995) for plants; Loftus and Scherf (1993) for livestock.)

germplasm exist world-wide (IPGRI 1995; Table 13.4-4), some are replicates, poorly documented and poorly preserved. It is probable that a high percentage of these accessions have lost their viability. While gene banks and other *ex situ* strategies have often been recommended as part of integrated wild plant conservation programmes (e.g. Frankel and Soulé 1981; Given 1990; Falk 1992; Heywood 1992b), wild species now account for fewer than 2% of total germplasm accessions (Astley 1991). Ashton (1987), however, warns that *ex situ* strategies should be considered carefully if they are to complement, not compete with, *in situ* conservation efforts. Hamilton (1994), moreover,

demonstrates that releasing seed-bank genotypes in natural populations can depress population fitness if the seed-bank material does not contain genotypes of high relative fitness in the introduction habitat.

Nevertheless, one collection in one gene bank may hold the special characteristics needed to deal with a new disease or pest. If this gene were not available, an entire crop species might face catastrophic failure, as has occurred in certain geographic regions for crops such as rice, maize, potatoes and citrus.

During the 1970s and early 1980s, collecting germplasm and adding accessions were the highest priorities for many gene banks. The characterization and evaluation of the accessions lagged far behind the collecting, and still does. Therefore, a low percentage of the stored germplasm has actually been incorporated into breeding programmes, and complete characterization and evaluation of existing accessions is probably impossible.

To overcome the problems associated with the gap between collection size and capacity for characterization and evaluation, it has been suggested that representative samples – between 10 and 20% – of the large collections should be taken and characterized to form smaller ‘core collections’ (Frankel and Brown 1984; Lleras *et al.* 1994; Hodgkin *et al.* 1995). The core collections would then be characterized and evaluated in detail, and steps taken to incorporate them into breeding programmes. Core collections are now being established for rice, corn, cassava and several other species. During the next few years, core collections will probably be extended to all crop species, including wild relatives of crop species (Hodgkin *et al.* 1995).

At the International Workshop for Core Collections held in Brasilia in 1992, Lleras (1994) also proposed that *in situ* or field gene banks should be established for biodiversity conservation areas (e.g. protected areas, key areas where traditional agriculture is practised, etc.). These could serve as core collections for plant species associated with the individual conservation areas, giving rise to an *in situ* core collection strategy.

13.4.3.3.4 Ex situ technologies. A growing range of technologies and strategies are available to conserve species and genetic resources *ex situ* (see also Sections 2 and 8). Table 13.4-5 presents an overview of *ex situ* conservation strategies used for animal species, and Table 13.4-6 provides the same for plant species, with some species examples provided for each strategy. For plants, botanical gardens and seed banks are the traditional forms of off-site conservation, and they maintain the bulk of the collections. Gene bank standards for conserving orthodox seeds have been established (FAO and IPGRI 1994): however, for recalcitrant species (those having seeds that do not tolerate drying or storage at low temperatures), live collections in field gene banks are one alternative. For

animals, the maintenance of live collections of breeding stock (or breeding nuclei) has been the traditional strategy.

For animals, it is estimated that a breeding population of approximately 250 individuals is necessary to maintain 95% of the genetic diversity produced through 50 generations (Dresser 1988). Similar figures can be found for plants (Marshall and Brown 1975). The limitations of conserving such large populations *ex situ* have been emphasized repeatedly. These limitations include the costs of establishing and maintaining the *ex situ* facilities, and damage by pests, diseases and natural and human-made catastrophes (Plucknett *et al.* 1987).

More sophisticated techniques have been developed during the past 30 years. Biotechnology has provided many new conservation tools and *in vitro* culture for both plant and animal species is rapidly becoming one of the more attractive alternatives. As knowledge of the physiology and genetics of various organisms increases, it is likely to be possible to extend the application of biotechnology to the conservation of a wide range of plant and animal species. Currently, limitations include the difficulty of producing whole new individuals from tissues and cells, and the possible incidence of somaclonal variation (i.e. spontaneous mutations of cells growing in tissue culture without any sexual process involved). The start-up cost may be relatively high for *in vitro* conservation (Plucknett *et al.* 1987; Lleras 1991), but continuing costs can be competitive with alternative methods such as field gene banks. Technology transfer and adaptive research will be needed to make *in vitro* conservation more accessible and applicable. These problems are gradually being solved through intensive scientific efforts.

Cryopreservation in liquid nitrogen at -196°C is also a promising alternative for both plant and animal species, although it is now largely experimental. The major advantages of cryopreservation over conventional techniques are an absence of complicated temperature and humidity controls, freedom from pest and pathogen damage, and indefinite viability with no genetic damage (Dresser 1988; Wang *et al.* 1993). For animal species, embryos and semen are used in cryopreservation. Seeds, embryos, or tissues may be used in plant cryopreservation. Cryopreservation may prove to be cheaper than the maintenance of growing cultures, since it will make long-term, even indefinite, conservation possible.

Another emerging and very promising technique is the conservation of isolated DNA. Among its advantages are that only minute quantities of material are necessary for conservation and the possibility of reintroducing the material into related genotypes or species. It can be used for endangered or even extinct species by taking samples of material from hair, bones, herbarium specimens or other material of the target species (Wang *et al.* 1993). However, at present this approach is even more experimental than

Table 13.4-5: Ex situ conservation strategies: animals.

Strategy	Species
Wild animals	
Short-term propagation and reintroduction	Golden lion tamarin, cheetah, wolf, red wolf, bison, Arabian oryx, onager, Andean condor, bald eagle, peregrine falcon, black-footed ferret, Hawaiian goose, Galapagos giant turtle, Galapagos land iguana
Long-term propagation	Lion-tailed macaque, Siberian tiger, Père David’s deer, European bison, Przewalski horse, Edward’s pheasant, Grévy’s zebra, addax, Chinese alligator, Aruba rattlesnake
Reintroduction, relocation	Koala, mongoose lemur, brown lemur, several spp. of primates, common marmoset, black rhinoceros, African elephant, several deer, moose, 400 spp. of birds, many reptiles and amphibians
Fostering, cross-fostering	Peregrine falcon, bald eagle, whooping crane, masked quail, polar bear (captive), many waterfowl, pigeons, cranes, passerine birds in captivity
Artificial incubation	Gharial, Siamese crocodile, Chinese alligator, green turtle, several cranes, many birds, reptiles and fishes
Artificial rearing	Hundreds of species of vertebrates
Artificial insemination	Alligator, ocellated turkey, brown-eared pheasant, whooping crane, squirrel monkey, yellow baboon, giant panda, guanaco, Speke’s gazelle, gemsbok, bighorn sheep
Cryopreservation	Semen of over 200 species, mostly untested
Embryo manipulation	Guar, bongo, eland, common zebra, Przewaski horse, cottontop marmoset, yellow baboon
Domestic animals	
Cryopreservation:	
Semen	Cattle, sheep, goats, horses, asses, camelids, rabbits, pigs
Embryos	Cattle, sheep, goats, horses, asses, camelids, rabbits
Surrogate mothers	Cattle, sheep, goats, horses, asses, camelids, rabbits
Embryo manipulation	Cattle, horses, asses, rabbits
Artificial insemination	All livestock species
Breeding nuclei	Buffalo, cattle, sheep, goats, horses, asses, pigs, camelids, poultry

Adapted from Conway (1988).

cryopreservation and should be viewed only as a future option for the conservation of genetic diversity. Indeed, conservation of DNA at low or ultra-low temperatures is now a routine process, but regeneration of whole organisms or even expression of particular genes in related genotypes/species is very difficult.

Table 13.4.7 summarizes the advantages and disadvantages of *in situ* and *ex situ* conservation strategies and technologies. Both are vital to an integrated biodiversity management programme (Figure 13.4-4).

13.4.4 Restoration and rehabilitation of species, populations and ecosystems

Widespread degradation of natural ecosystems is occurring world-wide as a result of human-induced activities such as

fragmentation, livestock grazing, logging and invasions by feral animals and plants. These factors often result directly in declines in populations, extirpation or extinction of species, and can eventually cause the disappearance of entire ecosystems. There is an increasing recognition world-wide that reintroducing endangered species and restoring and rehabilitating degraded ecosystems will play an essential part in maintaining and enhancing biodiversity (Cairns 1988, 1993; Jordan *et al.* 1988; Buckley 1989; Saunders *et al.* 1993; Olney *et al.* 1994).

13.4.4.1 Restoration of species and populations

Reintroduction of captive-bred species is often the justification for and logical end point of many *ex situ* conservation

Table 13.4-6: Ex situ conservation strategies: plants.

Strategy	Species
Domesticated plants	
Seed banks	All ‘orthodox’-seeded crops and many forestry species
Field gene banks	Many ‘recalcitrant’-seeded species, many clonally propagated species, some forest tree species
<i>In vitro</i> conservation (cells or tissues outside organism)	Many ‘recalcitrant’-seeded crops, including some forestry species, tuber crops and many clonally propagated species
Cryopreservation	Date and African oil palms, potato, chickpea, sugar cane, pollen of many species, seed of many orthodox species
Wild plants	
Propagation and reintroduction	Several hundred species of flowering plants
Gene banks	Several thousand species of flowering plants
Botanical gardens and arboreta	As many as 80 000 species of flowering plants and ferns

Adapted from Plucknett *et al.* (1987); Wang *et al.* (1993).

efforts. Three basic approaches are used to establish new populations of plants and animals (Primack 1995):

1. **Reintroduction programmes** release captive-bred or wild-collected species into an area of their historic range where the species no longer occurs. The objective of such programmes is to create a new population in the original environment.
2. **Augmentation programmes** seek to release individuals into an existing population to increase its size and genetic diversity. This is not normally recommended by IUCN (1994c) because of the possibilities of introducing disease and reducing the genetic fitness of the existing population. It may be necessary, however, where genetic diversity has been severely eroded.
3. **Introduction programmes** establish animal or plant populations outside their historic ranges. This may be appropriate where habitat conditions in historic ranges are severely degraded and the species can no longer survive there, or when the factor causing the loss of the species is still present, making a reintroduction programme impossible. The risks of such efforts, both to the introduced animals and to other species with which they would interact, need to be studied carefully.

The restoration of species is often expensive and extremely difficult. For example, programmes run by the

US Fish and Wildlife Service to capture, raise, monitor and release California condors, peregrine falcons, and black-footed ferrets have taken years and cost millions of dollars (Primack 1993). This can lead to criticism that such efforts are too costly, or unnecessary, or unethical. Well-run, well-designed reintroduction programmes, however, are the best hope for preserving species that are critically endangered or possibly already extinct in the wild. Two factors are particularly important to the success of species restoration programmes, especially animals. First, without public support, reintroduction programmes can easily fail due to the taking of a few animals or the objections of landowners to releases (Reading and Kellert 1993). Second, animals raised in captivity may lack the social skills to interact with other members of their species. These skills may include finding food co-operatively, sensing danger, finding mating partners and raising young, and could be essential to survival in their natural environment. Development of social skills with wild animals, therefore, is often crucial to the success of species restoration efforts (Primack 1993).

While reintroduction, augmentation and introduction programmes for common game species have been widely and often successfully implemented, success with threatened species is limited. Griffith *et al.* (1989) reported that the success of programmes in establishing new populations was:

- greater for game species (86%) than for threatened species (44%);

Table 13.4-7: Advantages and disadvantages of in situ and ex situ plant conservation methods.

Conservation strategy	Advantages	Disadvantages/difficulties
<i>In situ</i> : Protected areas and managed resource areas	<ul style="list-style-type: none">– Conserves genetic resources in their natural habitat, maintains interactions with other species and organisms;– Conservation of intraspecific variation can be combined with various degrees of conservation of interspecific variation;– Applicable to species with orthodox and recalcitrant seeds, and to vegetatively propagated species.	<ul style="list-style-type: none">– Space required;– Resources prone to loss by accident, pests, diseases;– A network of spatially separated conservation areas is required to capture provenance (clinal, geographical) variation of target species;– Information required on management interventions needed to meet specified conservation objectives.
<i>Ex situ</i> : Seed banks	<ul style="list-style-type: none">– Propagules readily available for use;– Minimum work; little space required (small seeds);– Provenance (clinal, geographical), variation can be conserved provided species range adequately sampled.	<ul style="list-style-type: none">– Not applicable to species with recalcitrant seeds, nor to vegetatively propagated species;– Space required (large seeds);– Does not conserve associated species in the ecosystem;– Regular regeneration of seedlots poses insurmountable problems at times.
<i>Ex situ</i> : Pollen banks	<ul style="list-style-type: none">– Minimum space required;– Applicable to species with recalcitrant and orthodox seeds;– Provenance (clinal, geographical), inter- and intraspecific variation can be conserved provided species range adequately sampled.	<ul style="list-style-type: none">– Only half of the genome conserved;– Tri-cellular pollen storage extremely difficult;– Needs female flowers for conventional propagation;– Propagules not readily available;– Does not conserve associated species.
<i>Ex situ</i> : Tissue culture banks	<ul style="list-style-type: none">– Minimum space required;– Genetic erosion reduced if methods such as cryopreservation are used;– Applicable to species with recalcitrant and orthodox seeds and to vegetatively propagated species;– Provenance (clinal, geographical), inter- and intraspecific variation can be conserved provided species range adequately sampled;– Aseptic conservation (minimizes disease risk);– Time required to produce propagules for use is short.	<ul style="list-style-type: none">– Sampling problems (within plant and sampling of adequate number of representative plants);– Protocols are species and at times genotype-specific;– Problems of somaclonal variation and early maturation;– Does not conserve associated species.
<i>Ex situ</i> : DNA banks	<ul style="list-style-type: none">– Minimum space required, large numbers of samples can be handled;– Applicable to species on the verge of extinction (or extinct).– Applicable to all kinds of plants.	<ul style="list-style-type: none">– Impossible at this time to get whole genome into another living organism/plant;– Not a practical germplasm conservation method <i>per se</i>;– Last recourse.
<i>Ex situ</i> : Seedling banks, <i>Ex situ</i> : Conservation stands	<ul style="list-style-type: none">– Applicable to species with recalcitrant and orthodox seeds;– Provenance (clinal, geographical), inter- and intra-specific variation can be conserved provided species range adequately sampled.	<ul style="list-style-type: none">– Space required;– Requires spatial isolation to conserve provenance identity;– Does not conserve associated species;– Generally not a preferred alternative for species with orthodox seeds, or those without actual socioeconomic value, due to economic considerations.
Botanical gardens and arboreta	<ul style="list-style-type: none">– Applicable to species with recalcitrant and orthodox seeds and to vegetatively propagated species;– Provenance (clinal, geographical), inter- and intraspecific variation can be conserved provided species range adequately sampled;– Useful method for unique phenotypes/genotypes (e.g. mutants, variants, sterile trees).	<ul style="list-style-type: none">– Space required;– Resources prone to loss by accident, pests, diseases;– Does not conserve associated species;– Not apt for the conservation of provenance (clinal, geographical) variation;– Requires a minimum number of individuals larger than needed to conserve interspecies variation which is generally the purpose of botanical gardens and arboreta.

Adapted from Wang *et al.* (1993).

Figure 13.4-4: Integrated approaches to biodiversity conservation. (Source: WRI/IUCN/UNEP 1992.)

- greater for release in excellent quality habitat (84%) than in poor quality habitat (38%);
- greater in the core of historic ranges (78%) than at the periphery of or outside historic ranges (48%);
- greater with wild-caught animals (75%) than with captive bred animals (38%); and
- greater for herbivores (77%) than for carnivores (48%).

Beck *et al.* (1994) conducted a survey looking only at captive-bred animals released within historic ranges. Success was defined as a self-maintaining population of 500 animals. On this basis, only 16 out of 145 reintroduction projects were judged successful. They concluded that releasing large numbers of animals over many years was a key to success: a finding somewhat at

odds with Griffith *et al.* (1989), who found that success increased with the number of released animals up to 100, but an additional 100 animals released did not further enhance the probability of success. More monitoring of release programmes is needed to determine whether or not such efforts are meeting their goals.

13.4.4.2 Ecosystem and landscape restoration

Restoration ecology is one of the newest and most challenging disciplines in ecology, although some ecological restoration efforts have been ongoing for decades. At the University of Wisconsin, six decades of work to restore an example of the North American tall-grass prairie – one of the most endangered major ecosystem types in the world – illustrate the complexity of this task (Jordan 1988). A variety of techniques, combined with hard work and experience, were crucial to the success of this effort.

The definitions of terms for restoration and rehabilitation vary considerably, and different terms are often used synonymously. *Rehabilitation* involves the repair – not the re-creation – of damaged ecosystems, while *restoration* usually involves the reconstruction of a natural or semi-natural ecosystem on degraded or modified land. Figure 13.4-5 illustrates the relationship between rehabilitation and restoration. Because these terms are sometimes used interchangeably, it is important to examine the context within which the words are used. Restoration and rehabilitation present unusual opportunities for co-operative and interdisciplinary efforts by a wide range of specialists from landscape ecologists and conservation biologists to environmental engineers and genetic resource specialists. This means that species reintroduction programmes and ecological restoration and rehabilitation efforts are often some of the strongest bridges between *ex situ* and *in situ* conservation programmes.

Rehabilitation of degraded ecosystems involves two major components. First, the factors leading to degradation must be treated. Second, components of the ecosystem that have disappeared have to be replaced. The first component is essential to the success of rehabilitation: any attempt to restore an ecosystem still subject to degrading influences is akin to treating symptoms rather than causes. Thus, for instance, the reintroduction of fauna to an area has to be preceded by the removal of feral predators, and the control of invasive plants has to include treatment of the factors allowing weed invasion to occur (Hobbs and Mooney 1993).

Replacement of components lost from the system may include the replacement of individual species (reintroducing species either from other nearby locations or from *ex situ* conservation facilities), or the replacement of entire communities. It may also involve the re-initiation of processes that have ceased, such as regeneration or recruitment of non-reproducing species. Common

Figure 13.4-5: The goal of ecosystem restoration is to fully recover the species composition and ecological complexity of the original ecosystem. Rehabilitation seeks primarily to improve ecosystem function (e.g. biomass production and nutrient cycling), with only partial recovery of species diversity and ecological complexity. (Source: Bradshaw 1990.)

components of rehabilitation programmes include the improvement of soil structure, the control of invasive plants, and the provision of structural habitat components (e.g. Berger 1990).

Ecosystem restoration has mostly been practised on extremely degraded sites such as mine sites, spoil heaps and municipal dumps (e.g. Bradshaw and Chadwick 1980; Majer 1989; Ward *et al.* 1990). Here again, the process involves some degree of amelioration of factors preventing the re-establishment of native biota (e.g. soil chemistry or structure, microclimatic factors, etc.) and the reintroduction of a subset of the biota. Frequently, restoration involves primarily the replacement of the plant community, generally by plantings and taking care of perennial species, in the hope (or belief) that fauna will return thereafter. Increasing efforts are also being made to re-establish animal and soil communities as part of the reintroduction process.

Although the goal of restoration is usually to return an area to natural conditions, too often little thought is given to exactly what this means, or what criteria should be used to judge success. Given the dynamics and fluctuating species composition of natural ecosystems, it is probably impractical to restore all the species or ecosystem components that may have existed before the system was degraded. Nevertheless, there are a few guidelines that can be used to guide restoration practices such that resilient (self-sustaining) ecosystems of comparable biological diversity are restored. For example, where restoration simply seeks to return some sort of vegetation to a previously vegetated area, there is little evidence that the restoration of the original biological community will

succeed. Bradshaw and Chadwick (1980) demonstrate that restoring soil nutrient status is often the key to restoring the original diversity.

In extensively fragmented landscapes, ongoing losses of species and degradation of natural ecosystems indicate that the existing fragments are not sufficient to maintain biodiversity in the long term (e.g. Saunders 1989, 1990; Kattan *et al.* 1994). The only solution to this problem is the large-scale restoration of the landscape as a whole, rather than at the scale of individual fragments. This involves restoration or rehabilitation actions for most parts of the landscape, including lands used for agriculture, forestry and other purposes, and modification of production practices so that conservation issues are considered. Box 13.4-5 summarizes experience in Costa Rica restoring tropical dry forest – one of the most threatened forest ecosystems in the world.

Only basic guidelines are available to plan and implement revegetation programmes so that they benefit biodiversity (Harker *et al.* 1993; Recher 1993). To be of conservation value, revegetation needs to enhance the existing system of fragments. Revegetation could be used to provide buffer zones around remnant areas, corridors between remnants, or as additional habitat (Hobbs 1993). In other words, landscape restoration aims at improving the design of the existing system of fragments by increasing habitat area and connectivity, and by providing buffer zones around existing fragments to protect them from external influences (see 13.4.2.2).

The aim is to produce a landscape with elements of the remaining natural ecosystems interspersed with restored ecosystems that fulfil some conservation objectives, and production systems that are sustainable and do not compromise the long-term persistence of the conservation areas (Lefroy *et al.* 1993; Main 1993). Landscape restoration thus has to consider the many characteristics of natural landscapes that may have conservation significance, including patchiness, connectivity and heterogeneity (Lambeck and Saunders 1993; Wiens *et al.* 1993).

The field of restoration ecology is in its infancy, although it has grown rapidly, with professional journals and a growing number of edited books on the subject. In view of our modest present capacity to predict ecosystem development following remedial measures, Cairns (1988) suggests that arresting and repairing widespread environmental damage may be less arrogant than presuming restoration and rehabilitation can effectively increase diversity. Clearer enunciation of the goals, techniques and theoretical framework of restoration ecology (Harker *et al.* 1993; Recher 1993) will lead to its inclusion as a major tool in biodiversity conservation.

13.4.5 Conclusion

Hand-in-hand with measures to use biodiversity sustainably are measures to protect ecosystems, species and genetic

Box 13.4-5: Restoration of a tropical dry forest in Costa Rica.

Dry tropical forests once occupied more than half of the forested terrestrial tropics (Murphy and Lugo 1986; Janzen 1988a). Today, in Central America they have been reduced to a few tattered remnants. Grazing, cultivation, fires and logging have converted these forests into pastures, fields and various kinds of highly altered successional vegetation. Ecological restoration is one of the few strategies left by which to maintain the biodiversity associated with this highly threatened forest type (Uhl 1987; Janzen 1988b; Nepstad *et al.* 1991; Brown and Lugo 1994).

To reverse the process of degradation, a small group of ecologists, local people and personnel from Costa Rica's National Park Service have begun an ambitious long-term project to fully restore the biodiversity of the 75 000 hectare Guanacaste National Park in northwestern Costa Rica (Janzen 1987; Allen 1988). This ecosystem, together with its adjacent cloud forest and rain forest where many dry forest organisms pass the dry season (which comprises the 110 000 ha. Guanacaste Conservation Area), contains about 60% of Costa Rica's biodiversity in only 2% of its national territory.

Restoration work began in 1985. After four centuries of European-style ranching, logging and hunting, the dry forest ecosystem still had virtually all of its several thousand native species. Poor soils, little rainfall, an absence of year-round water, and remoteness from political and economic centres had protected the area from the heavy exploitation that eliminated most other areas of tropical dry forest in the region.

Led by Dan Janzen, an ecologist with 20 years of research experience in the area, a foundation was established to assemble the Guanacaste Conservation Area (GCA) from a mosaic of semi-abandoned ranches, failed colonization schemes, diverted waterways, access roads, extensively grazed pastures, patches of secondary forest, and a small national park (Santa Rosa National Park). With support from more than 4000 individuals and institutions, the foundation established an endowment to support the management of the GCA and its restoration activities (Janzen 1988a).

The most important restoration activity is removing factors that cause ecological degradation or severe species decline. Eliminating these factors, such as fire (natural fires were extremely rare), poaching of animals and trees, intensive grazing, stream diversions and crop cultivation, will take centuries.

Eliminating fire as a degradation factor is perhaps the most challenging task. Using firebreaks, lookout posts, and engaging neighbours in the management of small brush and litter fires are part of the fire management strategy. Hunting is being controlled to rebuild populations of seed-dispersing birds and animals. Native trees are being planted and cattle grazing reduced to levels needed to control exotic grasses. Within the next 100 to 300 years, the goal is to eliminate introduced species and re-establish a forest ecosystem.

One innovative and critical part of this restoration effort is the active involvement of local people in many aspects of park management and restoration activities. Many of the farmers and ranchers living within the GCA have been given opportunities to be trained as park employees and use their skills and knowledge to help develop the park. Some are now being trained as park managers and biologists (Primack 1993).

The restoration of the area is a social and cultural enterprise as much as it is a biological one. 'Biocultural restoration', or the use of the GCA to teach the 40 000 local residents about natural history, and the principles of ecology and conservation, is a key element of the programme. Educational and research programmes have been designed and implemented in grade schools, secondary schools and universities. Janzen (1986) believes the long-term success of the effort depends on having residents become local and national advocates for the conservation of natural resources.

Already, results of the restoration efforts at GCA are noticeable. For example, with the cessation of fire, the approximately 30 000 ha of abandoned pastures are filling rapidly with wind-dispersed native plant species (Janzen 1990). Large grass stands are sprinkled with young shrubs and saplings projecting above the 1–2 m tall grass after five years of fire protection. Ancient pasture soils have regained a thick litter and high organic content in less than 10 years from the beginning of the reforestation process. Ecotourism and research interest in the GCA have developed rapidly, providing new opportunities for local employment and funding to meet the US\$1.2 million annual operating budget. The GCA, which is managed by a parastatal organization governed by a local board, employs a staff of 95, all of whom are Costa Ricans. The GCA demonstrates that restoration, thanks in large part to the vision, energy and common sense of a small group, can be a very good investment in the sustainable use and conservation of biodiversity.

diversity – either in place (*in situ* measures can be used at all biological levels) or in specially designed facilities outside natural habitats (*ex situ* measures can be used for species and genetic diversity). These measures are, in essence, means by which we can protect biodiversity against the failure of the sustainable use measures described in 13.3.

The most effective mechanism for conserving biodiversity, by almost any reckoning, is to prevent the conversion or degradation of habitat. The world's 10 000 protected areas have figured prominently in biodiversity conservation efforts around the world. Reasonably accurate data on the number and area coverage of protected areas are available for most countries, and gaps in the representation of major ecosystem types by country and biome are generally well understood. More specific information, however, on the effectiveness of protected areas in conserving elements of biodiversity is generally not available. For example, information on the biodiversity resident within protected areas, especially at the genetic level but even for plants and vertebrates, is inadequate for the vast majority of protected areas.

Protected areas around the world face a number of serious obstacles. First, protected areas, particularly in developing countries, have often yielded few economic benefits and have imposed substantial costs on local people leading to severe conflicts between conservation and economic development goals. Second, a lack of trained personnel, investment and scientific research together with the overlooked potential of protected areas as genetic resource reserves, providers of irreplaceable ecosystem services, and earners of tourism dollars, have limited the value and role that such areas can play in society. Third, while a few of the world's terrestrial biogeographic regions have approximately 10% of their area covered – a broad target established by the World Conservation Union (IUCN) – most biogeographic regions, especially marine regions, are poorly represented in the world's network of protected areas.

Protected areas – due to constraints on size, representativeness and management effectiveness – must be augmented by protective measures elsewhere. Fragmentation of natural ecosystems is generally seen as one of the most important threats to biodiversity world-wide. Protecting individual habitat fragments and natural habitat corridors within a matrix of more intensive human uses of the landscape is likely to be an important factor in the persistence of native biodiversity in many areas.

A wide array of techniques to conserve individual species, populations and genes must complement conservation at the landscape and ecosystem levels. These include both *in situ* (or on-site) measures targeted at individual species or sites of important genetic diversity and a growing range of *ex situ* (or off-site) methods.

Effective *in situ* approaches for the conservation of

targeted species include legal protection of endangered species; the preparation and implementation of management or recovery plans; and the establishment of protected areas specifically to protect the species or to protect unique genetic resources such as particularly important forest genetic resources. *In situ* management, however, faces two major limitations: (1) a lack of information on the conservation status and habitat needs of individual species, and (2) the considerable economic or opportunity costs of conserving individual species or populations.

A growing range of *ex situ* technologies associated with gene banks, zoos, botanical gardens and aquaria have rapidly expanded our capacity to preserve species and genetic diversity. None of the *ex situ* technologies – arboreta, aquaria, botanical gardens, seed banks, captive breeding units, clonal collections, microbial culture collections, field gene banks, forest nurseries, propagation units, tissue and cell cultures, zoological gardens, and museums holding seed banks or genetic material – are fail-proof. Depending on the technology used, they are vulnerable to pests and disease, physical damage to facilities from natural causes (e.g. fires, floods, storms, etc.) and human events (e.g. war, economic decline, policy change, etc.).

One way to compensate for the limitations of *ex situ* conservation measures is to deploy measures to restore and rehabilitate natural populations and ecosystems. A growing knowledge and capacity exists, that should make possible the reintroduction of certain species lost from ecosystems, restoration of certain ecological functions, and sometimes even the transformation of altered communities back to assemblages similar to their native state. *Rehabilitation*, which aims to revive important ecosystem services on degraded lands, has become an increasingly important element of resource conservation throughout the world. More ambitiously, *restoration* attempts to bring lands modified by human use or natural catastrophe back to their natural state. Because determining the 'pre-disturbance' state of most ecosystems is difficult and because ecosystems continually change, complete restoration is rarely a realistic goal.

Since rehabilitation and restoration techniques are still relatively new, considerable research is needed for most ecosystems, and it is rare that an ecosystem can be fully restored. Nevertheless, restoration and rehabilitation of ecosystems will come to play an increasingly critical role in coming decades as techniques for solving the problems caused by the current mis-management of biodiversity.

13.5 Social-economic strategies to sustainably use, conserve and share the benefits of biodiversity

13.5.1 Introduction

Social and economic strategies have become increasingly prominent in biodiversity planning (see, for example, WRI/IUCN/UNEP 1992). But many of these approaches are new to conservationists, and there is little experience in applying them to the sustainable use and conservation of biodiversity. Much of the discussion related to their use has therefore consisted of describing

examples of comparatively new or recent efforts, which are largely untested, as well as exhortations to take actions for which the full implications are not yet well understood.

Conservationists need to enhance their appreciation of the impact of social and economic processes on the protection and sustainable use of biodiversity. They also need to explore thoroughly the potential for socioeconomic tools and methods to complement other conservation policies and programmes. This chapter gives an overview of some of these challenges and opportunities, with an emphasis on their use at local and community levels.

13.5.2 Social interventions at local and community levels

Economic conditions and policies have a profound effect on the ability of people to use biological resources sustainably, to conserve them, and to share their benefits. Most of the underlying causes of biodiversity loss are found in national and international policies that undervalue natural resources, create incentives to over-exploit biodiversity, and widen the gap between the richest and poorest both within societies and between countries (see Section 12). Economic policies and tools used to address these problems at national and international levels are discussed in Section 12.7.

Some of the most effective tools for enhancing the sustainable use and conservation of biodiversity, however, are strategies to strengthen social involvement and participation in biodiversity management. Without local participation and support, many conservation and sustainable use efforts fail. This has been recognized by many in the conservation and sustainable development communities, and social components are now commonly found in biodiversity management projects. Still, the effectiveness of these efforts is poorly documented. In part, this is due to the difficulty of assessing the impact of social interventions. It is also true that most social components of biodiversity management programmes are relatively recent.

Two important types of social tools – the use of indigenous knowledge and strategies for local participation – are reviewed here. Their role in biodiversity management is then assessed in the context of community forestry and protected areas management.

13.5.2.1 Indigenous knowledge

Indigenous peoples with a historical continuity of resource use practices often possess valuable knowledge about the behaviour of complex ecological systems in their own localities. This knowledge has accumulated through a series of observations that stretch over many generations. Where indigenous peoples have depended on local environments for the provision of resources over long

periods of time, they often develop a stake in conserving biodiversity. Their practices for biodiversity conservation were built through lengthy trial and error processes. This implies an intimate relationship between the application of ecological knowledge with belief systems.

Such knowledge is difficult for Western science to understand. It is vital, however, that the value of the knowledge–practice–belief complex of indigenous peoples as it relates to biodiversity management is fully recognized. Conserving this knowledge might best be accomplished through promoting the community-based resource management systems of indigenous peoples (Gadgil *et al.* 1993). Several examples of such systems are presented below. See also Section 11, and 13.3.2, 13.3.3, 13.3.4 and 13.3.5 for techniques used in traditional management systems associated with agriculture, forestry, fisheries and the use of wild flora and fauna.

Brazilian Kayapo Indians at the southern edge of the rain forest develop forest islands or *apete*. Beginning as small vegetation mounds, these *apete* are carefully managed and supplemented as they grow with a complex species mix of medicinal plants, palms and vines. New *apete* fields reach peak production levels in 2–3 years, although some species, such as sweet potatoes, yams, taro, banana and papaya are productive for longer periods. Even when the primary crops disappear, old *apete* fields keep producing a range of useful products. They become heterogeneous forest patches, some managed for fruit and nut trees and for attracting wildlife (Posey 1985).

Runa Indian swiddens in the Ecuadorian Amazon resemble agroforestry systems rather than the slash-and-burn approach that merely results in a temporary clearing in the forest canopy. Compared to unmanaged fallows, such swiddens actually increase species diversity through the planting and protection of secondary species (Irvine 1989).

There is species diversity management in a number of traditional aquaculture systems. In some Chinese integrated agriculture–aquaculture systems, the fish are fed with agricultural wastes, and fish waste is used to fertilize crops. An example is the fish-farming system integrated with mulberry silkworm, vegetables and sugarcane production in the Zhujiang Delta (Ruddle and Zhong 1988). In Indonesia, traditional systems combined rice and fish culture. Wastes from such systems often flowed downstream into a brackish water aquaculture system or *tambak*. The *tambaks* themselves were polycultural ponds, often combining fish, vegetables and tree crops (Costa-Pierce 1988).

While the practices of habitat management by traditional agriculturalists are well known, knowledge about habitat management by hunter-gatherers is more controversial. But there is now evidence that Amerindians of Alberta, Canada, regularly used fire until the late 1940s to open up forest clearings and corridors to provide improved habitat for ungulates and wildfowl. Hunting success as well as

accessibility were improved by this method (Lewis and Ferguson 1988). Similar findings in Australia suggest that aboriginal hunters used fire to improve feeding habitat for game and to assist in the hunt itself (Lewis 1989).

Gadgil *et al.* (1993) argue that four kinds of indigenous conservation practices are of particular relevance to biodiversity conservation:

1. Total protection to individual biological communities, including ponds, meadows, pools along river courses, and forests. Throughout the Old World, forests were often protected as sacred groves. Protection provided in such refuges may have been an effective way of ensuring the persistence of certain species and biological communities.
2. All individuals of certain species of plants and animals may be afforded total protection. For example, *Ficus* trees are widely protected in many parts of the Old World. These trees are considered a keystone resource by ecologists. Local people are often aware of the importance of these trees as a refuge for a wide range of birds, bats and primates, and this understanding may have been converted into widespread protection of the *Ficus* tree at some point in the past.
3. Certain particularly vulnerable stages in the life cycle of an organism may be given special protection. The danger of over-harvesting and depletion is clearly greater if these species are hunted during their vulnerable stages, and the protection afforded them may be evidence of ecological prudence. For example, fruit bats may be hunted in south India when they are away foraging but not at daytime roosts, even when these are within villages.
4. Major events of resource harvesting are often carried out as a group effort. Many tribal groups engage once a year in a large-scale, communal hunt, which may help groups assess the status of prey populations and provide information needed to adjust harvesting levels.

Indigenous peoples have received much attention as potential resource managers of threatened tropical forest ecosystems, although they often lack control over their territory and resources (Davis and Wali 1993). But the question of what indigenous people and conservationists have in common is a highly controversial and emotional one (see Alcorn 1993; Redford and Stearman 1993). While there is general agreement that it is wise for conservationists to work with indigenous peoples, there is considerable difference of opinion over the extent to which the interests and agendas of the two groups are in harmony or in conflict. The process of change that many traditional groups are experiencing implies a restructuring of community institutions. Biodiversity in traditional lands

may ultimately depend on the existence and influence of these institutions (Brandon 1995b).

13.5.2.2 Local participation

The theory and practice of local participation in rural development have been well documented (e.g. Cohen and Uphoff 1977; Oakley 1991; Cernea 1991), and recently conservationists have begun to utilize the concept. But there is considerable debate about what participation actually means, as well as about its relationship with the protection and sustainable use of biodiversity. Careful reviews of participatory approaches to biodiversity management based on extensive case-study materials have been carried out by West and Brechin (1991), Wells *et al.* (1992), Wells and Brandon (1993), Brandon (1994), Brandon and Wells (1992) and Little (1994). Unless otherwise stated, the discussion in this section is drawn from Wells *et al.* (1992).

While many, if not most, biodiversity management projects now emphasize local participation, few projects have specified what they mean by participation, or how they expect local participation in project development activities to contribute to the sustainable use and protection of biodiversity. Thus, some uncertainty and ambiguity surrounds the issue of local participation and conservation, both in theory and in practice. It is important to ask *what* local people are participating in, *who* is participating, and *how* they get to participate.

Projects can be identified that deliver social and economic benefits to local people. Is this local participation? Most likely not. Local participation viewed as a process goes well beyond simply sharing in social and economic benefits. It has been described as 'empowering people to mobilize their own capacities, be social actors rather than passive subjects, manage the resources, make decisions, and control the activities that affect their lives' (Cernea 1991).

Projects may be classified on the basis of their approaches to and relationships with the intended beneficiaries. At one end are projects that perceive local peoples' involvement as passive – the 'beneficiary' approach. The goals of this approach to development are tangible economic benefits, although those who are to receive them have only a limited role in generating them. At the other end are projects that seek to involve people in the process of their own development, adopting a 'participatory' approach. In these projects, development is perceived as a way to empower people and improve their ability to control their lives and use and manage resources. The project is a catalyst to stimulate self-reliance among the poor and underprivileged. This approach emphasizes the role of local institutions – both formal and informal – in providing people with the means to control their lives.

Projects with a beneficiary orientation generally set their goals in terms of changes in readily measurable indices,

such as income levels, farm productivity, infant mortality rates and literacy rates. Project success is then gauged by improvements in these indices. The goals and measures of effectiveness in projects with a participatory orientation are more elusive. Eventually such projects seek to achieve goals similar to those of beneficiary projects; however, they are orientated more toward establishing a process leading to change that can be sustained after the project ends.

Paul (1987) summarized much of the literature on the participatory approach by suggesting that its objectives include increasing project effectiveness, increasing the capacity of beneficiaries to take responsibility for project activities, and facilitating cost-sharing through local contributions of land, money or labour. Others have pointed to the importance of involving stakeholders – intended beneficiaries – to give them a vested interest in, and presumably greater commitment to, achieving project goals. It is not easy to measure achievements against these kinds of objectives, particularly over short periods, while projects are still under way and before more tangible benefits have become apparent.

There are five main areas in which local people can participate in projects (Cohen and Uphoff 1977; Paul 1987; Salmen 1987):

1. **Information-gathering:** Project designers or managers both collect information from and share information with intended beneficiaries on the overall project concept and goals.
2. **Consultation:** Intended beneficiaries are consulted on key issues during the project. Beneficiaries have an opportunity to interact and provide feedback during project design, implementation, or both.
3. **Decision-making:** Beneficiaries participate in decision-making about project design or implementation, giving a greater degree of control and responsibility than the passive acceptance of possibly unwanted benefits.
4. **Initiating action:** When beneficiary groups identify a new need in a project and decide to respond to it, they are taking the initiative for their own development. This is different from acting or deciding on tasks or issues identified by the project.
5. **Evaluation:** Participatory evaluation by beneficiaries can provide valuable insights and lessons for project design and implementation – information that is otherwise likely to remain unknown.

A project may not have a consistent approach to participation that stretches across all of its components or activities. To use Paul's (1987) term, project components

may each have their own 'intensity' of participation. But local participation in conservation projects implies the consistent involvement of local people in strategic project issues rather than their occasional or limited involvement in day-to-day activities. Very few, if any, of the more than 50 projects studied by West and Brechin (1991), Wells *et al.* (1992), and Little (1994) can pass this test.

Two principal approaches to organizing and sustaining community participation in projects can be identified: employing agents of change and building local institutions.

1. **Agents of change.** Agents of change are also referred to as field workers, extension workers, community organizers or animators. Paul (1987) distinguishes two categories: field workers employed by the agency implementing the project, and workers or volunteers from among the beneficiaries who act as community mobilizers. Ideally, agents of change do not act as leaders and do not tell the community what to do (Midgley 1986; Tilakaratna 1987). Their task is to foster grass-roots participation and build local institutions. Examples of agents of change in biodiversity conservation are shown in Box 13.5-1.
2. **Institution building.** It has been argued that local participation through institutions or organizations is more likely to be effective and sustained than individual participation (see, for example, Uphoff 1991). Local institutions can act as a focus for mobilization among local people and as a link between local people and external organizations, whether governmental or non-governmental. Institution-building has been defined by Midgley (1986) as 'the creation of procedures for democratic decision making at the local level and the involvement of local people in these procedures to the extent that they come to regard them as the normal way of conducting community affairs'. Examples of project attempts to build local institutions are included in Box 13.5-2. Most of these institutions are of relatively recent origin and few, if any, have become independent of the projects.

For a conservation project to achieve its basic objective – the protection and sustainable use of biodiversity – people can only be empowered in aspects of development, including local resource management, that do not lead to over-exploitation or degradation of the protected wildlife and wildlands. In practice, this can be very difficult to achieve using economic incentives. Conflicts of interest are inherent between rural people's ability to earn a living and the management of nearby protected areas. It is unrealistic to assume that resource-poor people, living next to what may appear to them to be limitless resources of land, trees, plants and animals, will readily support park protection

ideals. Projects can, and should, try to mitigate such conflicts of interest by promoting alternative income sources and education programmes. But the conflicts cannot be expected to disappear (Wells *et al.* 1992).

Despite much rhetoric to the contrary, most biodiversity conservation projects have treated local people as passive beneficiaries of project activities and have failed to involve them in the process of change and their own development. As a result, the targets of the projects often have no stake in or commitment to the activities being promoted. This apparent lack of progress is at least partly attributable to a project's relatively short duration and illustrates how lengthy and difficult a process eliciting local participation in any development project can be.

The limited experience to date suggests that at least a decade is likely to be needed, instead of two or three years as once thought. Such lengthy periods will require patience and commitment from donors, project managers and the intended beneficiaries. These long periods are also likely to be accompanied by a continued escalation of threats against the protected area that the project is trying to conserve. The need for patience can conflict with feelings of urgency about the need to change or stop destructive patterns of protected area degradation (Wells *et al.* 1992).

While participatory approaches to biodiversity conservation have yet clearly to demonstrate their effectiveness, participation can facilitate a more co-operative relationship between protected areas and local people and thus make law enforcement more humane and acceptable. A balanced approach would seem essential. In the long term, local participation should be sought as much as possible. However, short-term benefits also are needed to establish projects' credibility locally and to overcome distrust among the target population. The continuing need for law enforcement will have to be balanced between these long- and short-term goals. The appropriate nature of this balance for individual projects will depend on a thorough assessment of local social, political, economic, cultural and biological factors (Wells *et al.* 1992).

13.5.2.3 Methods of participatory inquiry

Methodologies of social assessment and participatory inquiry have the potential to help conservationists and others to find better ways of making participation truly participatory. In recent years there has been a rapid expansion in alternative methods of such inquiry. These methods have drawn on many long-established traditions that have put participation, action research, and adult education at the forefront of efforts to empower disenfranchised local people (Chambers 1992; Pretty 1994).

These new systems of inquiry represent a significant departure from standard practice. Some of the changes under way are remarkable. In many government and non-governmental institutions, top-down project design

blueprints are being superseded by investigation and analysis by local people themselves (Pimbert and Pretty 1994). There are some important common principles in these new systems of inquiry (Pretty 1994):

- A defined methodology and systematic learning process, with a focus on cumulative learning by all the participants.
- Multiple perspectives, seeking the diverse evaluations of different individuals and groups rather than characterizing complexity in terms of average values.
- Group inquiry process, implying three possible mixes of investigators: from different disciplines, from different sectors, and from outsiders (professionals) and insiders (local people).
- Context-specific inquiry, with approaches flexible enough to suit each new set of conditions and actors.
- The facilitation of experts and stakeholders to try to bring about changes that people in the situation regard as improvements.
- Inquiry leading to sustained action and implementable changes that represent an accommodation between different views, with actions including institution strengthening to increase people's capacity to initiate action on their own.

The range of participatory methods in use has increased dramatically in recent years (e.g. Mascarenhas *et al.* 1991; Chambers 1992; Pretty 1994). The methods are structured into four classes: (1) for group and team dynamics, (2) for sampling, (3) for interviewing and dialogue, and (4) for visualization and diagramming. Data gathering and analysis techniques that are generally applicable to the social assessment or participatory inquiry linked to biodiversity conservation projects are illustrated in Box 13.5-3.

Local people using the methods of participatory inquiry have shown a greater capacity to observe, diagram and analyse than most professionals had expected (Pimbert and Pretty 1994). In some programmes, this has led to village analysts conducting investigations without outsiders being present (Shah 1992). In such cases, participatory methods become the locally owned means to collective action.

Participatory Rural Appraisal (PRA) is a term becoming increasingly familiar to conservationists. PRA is a collective term for a growing list of approaches based on interactive learning, shared knowledge, and a flexible yet structured analysis. The methods are applied in the field by a multidisciplinary team and are designed to quickly generate new information on, and hypotheses about, local conditions and livelihoods. According to PRA practitioners, appropriate behaviour and attitudes allow outsiders to establish rapport, convene, catalyse, facilitate,

Box 13.5-1: Agents of change in biodiversity conservation projects.

Air-Tenere National Nature Reserve, Niger: The project established a network of village representatives from among pastoral communities. The selected representatives are people recognized locally as having authority within their herding groups. Their tasks are to be well informed about the rules, goals and activities in the reserve; to encourage others to support these rules and goals and to inform enforcement authorities of any infractions of the rules observed within their districts. These representatives receive no remuneration from the project, although they attend an annual workshop sponsored by the project.

East Usambara Mountains, Tanzania: To promote interaction with local communities, the project selected a village co-ordinator from each of 15 target villages. The regional government pays the village co-ordinators' salaries and has guaranteed to maintain the positions permanently. The village co-ordinators are the primary link between the project and the villages, meeting monthly as a group to report progress and problems. They are either trained by the project or sent to attend short courses. The village co-ordinators have begun working closely with farmers in their own villages, and most have established agricultural demonstration plots.

Khao Yai National Park, Thailand: At Sup Tai village, the principal agent of change is the full-time project manager from the Population and Development Association, the implementing non-governmental organization. This manager has hired a small number of local staff but works directly with villagers on project activities. The Population and Development Association has been active in thousands of villages throughout Thailand, and its field personnel are well educated and trained, with extensive community development experience.

South Luangwa National Park, Zambia: The main local agents of change are the village scouts. These are young men selected by local chiefs who are employed by the National Park and Wildlife Service and trained in wildlife enforcement. Hiring game scouts from local villages has been an effective way of generating community support for reducing poaching. The next stage of the project calls for hiring some 50 community facilitators to monitor socioeconomic effects and to involve the more disadvantaged members of the community, especially women.

Talamanca Region, Costa Rica: The project began a community technicians' programme in 1989 with representatives from each of 40 communities where nurseries have been established. The programme is intended to develop local leaders who can provide information on agricultural and agroforestry development and can act as liaisons between their community and outside agencies. Each community selects a representative, plus a deputy, to receive advanced training in agriculture and agroforestry. Representatives tend to be younger, better-educated members of the community. When they return to their villages, they train others in what they have learned, often on an individual basis. Farmers work on the community technicians' land in exchange for the time they receive from the community technician.

adapt, watch, listen, learn and respect. Meanwhile localpeople's sense of empowerment grows as they map, mode, diagram, interview, quantify, rank and score, inform and explain, show, discuss and analyse, plan, present and share their knowledge and experience with others (Pimbert and Pretty 1994).

The application of PRA and other new methods of participatory inquiry to biodiversity conservation will be of great interest to conservationists. International donor agencies are now beginning to incorporate the use of social assessment and participation techniques into the design of biodiversity conservation projects. For example, the World Bank (1994) has developed a set of guidelines to assess

how social factors such as capacity for local participation, tenurial rights, customary controls that regulate access to resources, gender roles in conservation, and community organization can be addressed in designing, implementing and monitoring projects. These guidelines are being tested in the design and implementation of GEF projects in India, Ecuador and Ghana. Results from those experiences will be used to revise and finalize guidelines that apply to all biodiversity conservation projects supported by the World Bank. Guidelines for monitoring and evaluating GEF projects, including socioeconomic and participation considerations, have also been developed (GEF 1992). While these guidelines are generic, and

Box 13.5-2: Institution building in biodiversity conservation projects.

Annapurna Conservation Area Project, Nepal: The project promoted the establishment of forest management committees and tourist lodge management committees. The forest management committee has helped re-establish community control over local forests, as existed prior to nationalization in the 1950s. Both the lodge and forest management committees have made some key resource management decisions.

Central Selva Region, Peru: The Amuesha Indians formed a six-person committee to determine the best structure for organizing forestry activities. The committee consisted of one representative from each of five communities and the proposed forestry activities administrator. A co-operative structure, similar to Amuesha communal government systems, was selected and shortly thereafter, members from the five communities joined to establish a forestry co-operative. Members participate in working groups, and the heads of working groups make decisions collectively.

Khao Yai National Park, Thailand: Project development and conservation activities at each village are centred on the environmental protection society. These institutions were created to enable villagers to take control of resource management and to encourage them to take some responsibility for safeguarding the national park. Considerable emphasis has been placed on establishing the credibility of the environmental protection society as a viable organization separate from the project centres.

Boscosa Project, Costa Rica: The project has helped establish or strengthen numerous small, local organizations throughout the Osa Peninsula. These organizations include a locally organized co-operative whose ultimate objective is to process wood into low-priced furniture, and agricultural producers' associations in three different communities. The project has also tried to strengthen existing community groups. Project staff have trained local communities in programme development, proposal writing and fund-raising.

Talamanca Region, Costa Rica: The project helped create the Talamanca Association of Small Producers (APPTA), a regional procurement, processing and marketing association. The association was established in 1987 and is administered locally by farmers involved in the project. It is one of the few regional sources for procurement of agricultural inputs or marketing assistance. User groups have been established for community nurseries and women's organic-farming groups. About 600 households in 40 communities have decided to participate. Each group decides how to organize the work, what seedlings to establish, the labour contributions from members, and so on.

experience with them is limited, their existence confirms the importance of participation and other social factors in conservation programmes. International NGOs are also devoting considerably more resources to social assessment in the planning, implementation and monitoring of biodiversity conservation projects (see, for example, BSP 1995). Assuming such guidelines are implemented effectively, a much larger body of evidence will be available in a few years' time to assess how social mechanisms can best be used to benefit both biodiversity and development needs.

13.5.2.4 Community forest management

Throughout much of South and Southeast Asia, communities have relied historically on their own rules and regulations to control forest use and to ensure equitable distribution of forest lands and products for agriculture, hunting and gathering. Community-based resource

management is generally possible in situations where members are able to carry out basic functions themselves, including the establishment of use regulations, the resolution of disputes, and the equitable distribution of benefits. Unfortunately, in many parts of Asia, the role of indigenous communities' institutions and leaders has been displaced by formal, often politicized, governance institutions. Lessons now emerging indicate that local community institutions need to be acknowledged and given the authority to take on responsibilities for forest protection. In some areas, small informal groups – often tribal – are taking action unilaterally by protecting forests against all outside users. Other groups are receiving support and encouragement from government forest agencies (Poffenberger and McGean 1994).

Over the past five years, India's forestry sector has begun shifting its strategies to emphasize the empowerment of communities as protectors of natural forests in order to

facilitate their regeneration and recapture their productivity. Under the Indian Joint Forest Management (JFM) concept, local communities become partners in protecting and managing state-owned forest resources, thus legitimizing a role in the control of resources that they have often held for generations (see also 13.3.3.1). Successful experiments were undertaken by Forest Department officials in West Bengal, Gujarat, and Haryana states from as early as 1972. In these cases, village Forest Protection Committees (FPCs) – or hill resource management societies in Haryana – were given the responsibility of protecting degraded forest land from illegal cutting, fires, overgrazing and encroachment. In return they were granted access to a range of non-timber forest products and in one case were granted 25% of the net return of the timber harvest (Campbell 1992).

The legal basis for JFM lies in India's National Forest Policy of 1988. Reversing almost a century of official policy, this document stated that forests were no longer to be commercially exploited to meet industrial needs. Instead, they are to be maintained to conserve soil and the environment, and to meet the subsistence requirements of the local people. The Ministry of Environment and Forests issued policy instructions in 1990 to all of the state forestry departments that supported greater participation of village forest communities and NGOs in the regeneration and management of degraded forest lands. These guidelines emphasized the increasing importance of jointly managed forest systems centred on the needs of forest communities, and on granting communities certain rights on regenerating

forest lands (Poffenberger 1990; Campbell 1992; SPWD 1992).

By early 1994, 15 Indian states had ratified the national guidelines and government orders supporting community empowerment for the management of public lands. But only a very small proportion of India's forests have come under effective access controls, and current policy only allows for communities to protect degraded forests. Thus, a major gap continues to separate plans and policies from field realities. But while progress is being made, opportunities should still be sought to expand community-forestry department partnerships beyond degraded forests to include well-stocked forests, parks and other resources of high value, including biodiversity value (Poffenberger and McGean 1994).

A recent national inventory in Thailand conducted by the Royal Forest Department found nearly 12 000 community forest management initiatives. These included both traditional community institutions created to manage forests for cultural, hydrological or production purposes, as well as more recently established organizations promoted by schools, temples and other local institutions. In Dong Yai, Thailand, 11 rural communities have worked together with regional foresters and researchers to protect and regenerate former *kenaf* fields. A remarkable transformation has taken place over 25 years, producing the largest dipterocarp forest in Northeast Thailand. Each community has organized a protection group that patrols a section of the 4000 hectare forest, monitoring for fires and timber exploitation by outsiders. Elaborate rules developed by the communities limit wood extraction to domestic needs only, while the collection of non-timber forest products such as mushrooms and gum remains open to outsiders from as far as 60 kilometres away. Strong community leadership and sympathetic foresters have played a key role in encouraging these villagers to take responsibility for and pride in the ecological health of their forests (Poffenberger and McGean 1994).

A number of challenges face forest departments, NGOs and researchers working to facilitate the establishment of community forest systems. Developing an efficient and equitable process through which public forest land can be allocated to local communities for protection is essential. Where forest departments have succeeded in this effort, they have created a supportive environment in which communities can take the lead in reaching consensus on the assignment of responsibilities. Often, decisions over territorial forest boundaries are based on historic use practices, traditional rights and current needs. Communities usually have a better understanding of these criteria and the actors than do the staff of forest departments. Where villages take the first initiative in forest designation and mapping, decisions are more likely to be acceptable to local groups. In such cases, the role of forest departments is to

provide technical support in areas such as mapping, and to help legitimize the outcome (Poffenberger and McGean 1994).

Forest departments are confronted with major transitions as they move from traditional custodial and timber management roles to support roles in joint forest management activities. Protection duties are transferred to the community. Production activities shift from timber to multiple products, managed by villagers. Field staff need to develop a different mix of technical skills and technical expertise to serve as community organizers, forestry extension agents, and market analysts (Poffenberger and McGean 1994).

The Asia experience with community forest management reveals that elaborate policies and heavily funded projects are not necessarily sufficient to accelerate the empowerment of community groups as managers of public forests. Significantly, more critical is the emergence of a political environment supportive of facilitating the establishment and replication of decentralized management systems. Ultimately, simple transparent policies need to be developed as broad guidelines that provide flexibility and encouragement to local administrators and communities to fine-tune their own resource management agreements (Poffenberger and McGean 1994).

13.5.2.5 Local people and protected areas

People situated in or near biologically diverse ecosystems often gain little economic benefit from conservation or sustainable resource use. In contrast, the costs incurred as a result of conservation measures – especially the establishment of protected areas – tend to be felt most severely at local levels (Wells 1992). Measures designed to promote sustainable use or protection of biodiversity must therefore provide economic incentives to increase the net local benefits from sustainable resource use and protection (McNeely 1988; see also Section 12). Furthermore, it is increasingly recognized as neither politically feasible nor ethically justifiable to attempt to deny poor people the use of natural resources without providing them some alternative means of livelihood (Wells *et al.* 1992). Enlisting the co-operation and support of local people has thus emerged as a major priority for the management of protected areas.

An increasing number of projects have been launched in developing countries with the goal of linking biodiversity conservation with improvements in human welfare (see, for example, McNeely 1988; Kiss 1990; Stone 1991; West and Brechin 1991; Western *et al.* 1994). Led by the international conservation NGOs, these integrated conservation-development projects (ICDPs) have been based primarily on innovative land-use strategies, including biosphere reserves, multiple-use conservation areas, buffer zones on protected area boundaries, and a variety of other approaches (Wells *et al.* 1992).

Participatory approaches to linking biodiversity conservation with local social and economic development have proved enormously attractive to many of the NGOs, government departments, and international agencies involved in biodiversity conservation and sustainable development, including the Global Environment Facility (GEF) (Wells and Brandon 1993). A large proportion of the funds available for biodiversity conservation is now being committed to a variety of ICDPs throughout the developing world, and even more money is potentially available from GEF, from bilateral aid agencies, and possibly through other mechanisms associated with the Biodiversity Convention (Wells 1994).

But despite this dramatic increase in interest, some key questions remain unanswered (Wells 1995):

1. What has been learned about translating the *principles* of biodiversity conservation and sustainable development into effective on-the-ground *action*?
2. Can the lessons from promising local projects be used to increase the effectiveness of the larger-scale programmes that will be funded by the international development agencies?

Since the mid-1980s, NGOs have devoted increasing efforts and financial resources to Integrated Conservation and Development Projects (ICDPs). Most of these have been described as pilot or demonstration projects in recognition of their innovative approaches, limited funds and modest scale. But very few of these projects have so far been able to demonstrate significant improvements in biodiversity conservation that are attributable to, or even connected with, improved local economic opportunities (Wells *et al.* 1992). Unambiguously successful and convincing examples where local peoples' development needs have been effectively reconciled with biodiversity conservation remain difficult to find (Wells 1995). ICDPs therefore represent an extremely challenging approach that has so far generated few clear successes (Oldfield 1988; Sayer 1991; Brandon and Wells 1992; Wells *et al.* 1992; Western *et al.* 1994).

There are several reasons why progress in demonstrating the feasibility of ICDPs has so far been limited (Wells *et al.* 1992; Brandon 1994; Wells 1995). Most existing projects have been implemented on a very small scale, with little financial support, and with insufficient political backing. The projects have also been confronted, and often confounded, by policy and legal constraints originating far outside the individual projects' spheres of influence. Project objectives have often not been well defined, and because projects lack input from universities and professional researchers, few have been designed in such a way as to generate useful lessons.

Finally, the fundamental importance of involving local people, the intended beneficiaries, in all stages of projects has tended to receive more rhetorical than substantive attention. Apart from the problem of small scale, many of the constraints have proved equally difficult to overcome for the ICDPs supported by international development organizations, including the projects supported during the Pilot Phase of the GEF (Wells 1994; UNDP/UNEP/World Bank 1994).

Projects attempting to use social and economic incentives to strengthen biodiversity conservation often use a variety of activities aimed at eliciting local participation, intensifying land use, and increasing local employment, productivity and incomes – in other words, rural development. Rural development is a field with an immense amount of analytical literature and decades of field experience, much of it disappointing. But surprisingly few of the new generation of conservation and sustainable development projects appear to have learned much from the well-documented lessons of rural development or to have drawn sufficiently on organizations and individuals with experience in promoting long-term change in rural communities (Wells *et al.* 1992).

The very limited human and financial resources available to implement ICDPs have invariably been absorbed in addressing day-to-day, site-specific issues. As a result, there has been only limited use of the latest ecological and social science techniques, minimal attention to monitoring and evaluating progress, and little advancement toward the strategic objective of demonstrating the potential for systematic change on a meaningful scale (Wells 1995).

The practical reality of project experience has thus fallen short of the hopes and expectations for biodiversity conservation and sustainable economic development. This is in contrast to some optimistic plans and claims, and despite the efforts of many talented and dedicated people implementing field projects (Wells 1995). One reason may be that many of the underlying assumptions on which these projects have been based are so far unproven, and many are highly questionable (Brandon 1994; Wells 1995). Two of these optimistic assumptions will be considered briefly here.

First optimistic assumption: that biodiversity conservation is generally compatible with sustainable economic development. It is far from clear what trade-offs and choices need to be made in reconciling development with conservation or even whether the concept of sustainable development can be realized in practice (Ludwig *et al.* 1993; Robinson 1993). In conservation circles it has become fashionable to take it for granted that social justice and economic development are necessary preconditions for conservation (Soulé 1991), and that biodiversity conservation in the tropics is *de facto*

compatible with sustainable economic development. But simply to assume that people will be more inclined to conserve local biodiversity if their living standards improve, or that there are always methods to improve local incomes without depleting biodiversity is, at best, naive. In the haste to demonstrate some progress, many new programmes have been launched without adequate research or reflection on the circumstances in which biodiversity conservation and sustainable economic development are compatible, or even how these terms should be defined (Redford and Sanderson 1992).

This is more than an academic debate. Many biodiversity projects that have broadened to focus on local economic needs have lost sight of their original conservation goals and are unable to establish a coherent link between their conservation and development activities. In these circumstances it is often impossible to determine whether local development initiatives have a negative or positive impact on conservation. It is essential to clarify whether projects are attempting to improve local welfare through economic development as a principal objective or, more simply, as a means of enhancing biodiversity conservation (Brandon and Wells 1992). This distinction, which most existing projects have simply passed over, has profound implications for project design and implementation.

Second optimistic assumption: that a project-based approach can achieve conservation and sustainable economic development. A project-based approach has inherent limitations that are often overlooked. Factors leading to the loss of biodiversity include public ownership of extensive areas of land, unmatched by the capacity of government agencies to manage the land; powerful financial incentives that encourage resource over-exploitation; and laws, policies, social changes and economic forces over which poor communities in remote rural areas have no influence. The inability to change the parameters of the environment in which they are operating is a serious weakness of most projects. Even under the best of conditions, projects focusing on areas of high ecological value and targeting local populations can play only a modest role in mitigating the powerful forces causing environmental degradation (Barber *et al.* 1995). When these projects are also trying to develop new approaches with small budgets, inexperienced implementing organizations, and limited access to usable technology, and when the projects are constantly struggling for official recognition, their ambitions must realistically be limited (Wells *et al.* 1992). Individual projects must therefore be recognized as single components within broader-based conservation programmes that also include a variety of policy and institutional initiatives (Barber *et al.* 1995).

High priority should now be given to testing ways of translating the ICDP approach into more effective on-the-

ground action. This might be done through a long-term experimental learning process in biodiversity conservation and sustainable development (see Box 13.5-4). A small number of participatory conservation projects would be undertaken to systematically test and learn from field experiences, including the challenges of scaling up or linking together projects that seem promising at local levels. These experimental projects should reflect an in-depth understanding of the rural development experience, should be adequately funded, and should make strenuous efforts to decentralize strategic as well as day-to-day decision-making to local levels from the very inception of projects. Wherever possible they should be implemented by a mix of NGOs and government agencies, should encourage outside evaluation, and should collaborate with applied professional researchers to thoroughly document, analyse and communicate their results – both successful and unsuccessful (Wells 1995).

The current fascination of donors with ICDPs that combine biodiversity conservation with sustainable economic development is unlikely to continue indefinitely without some tangible demonstrations of progress. If serious long-term financial support to ICDPs is to be provided by conventional and mainstream institutions, it will be essential to find ways to come up with more concrete conclusions on project design and management, replicability, sustainability and cost-effectiveness during the next few years (Wells 1995). Otherwise, the call for biodiversity conservation with sustainable economic development is likely to remain no more than an attractive slogan.

13.5.3 Economic tools and incentives

This section provides examples of where local economic incentives have at least demonstrated their potential effectiveness in supporting biodiversity management objectives more efficiently than have traditional regulatory approaches. There are clearly important overlaps between the ‘social’ measures described earlier in this chapter and the ‘economic’ measures that follow, particularly at local levels. The examples and illustrations of economic incentives given here should therefore be read with frequent reference to the caveats and constraints already described in relation to social interventions.

Economic incentive approaches are those that rely on the price system and market forces to achieve their environmental objectives. Economic incentive approaches are highlighted in Article 11 of the Convention, which states that:

Each contracting Party shall, as far as possible and as appropriate, adopt economically and socially sound measures that act as incentives for the conservation and sustainable use of components of biological diversity.

The incentive-based approach to the protection and sustainable use of biodiversity attempts to improve decision-making that affects biological resources by improving markets for these resources. This approach recognizes that the conservation of biodiversity will be effective only if resource users are confronted with the true cost of their actions, and to the extent that the global and domestic values of biological diversity are appropriable by the individuals and societies who actually make the decisions concerning resource allocation (OECD 1994).

A wide array of economic incentive measures is potentially usable for the sustainable use and protection of biodiversity. In all cases, these economic incentive measures seek to improve markets for biological diversity, or create them where they did not previously exist. In some cases, this is achieved by giving value to biological diversity through compensation, penalties and improved resource pricing. In other cases, it is achieved by the removal of market distortions, improved market information, the introduction of systems of trading, and improved systems of property rights (OECD 1994; see Section 12).

To function effectively, incentives require some degree of regulation, enforcement and monitoring. They must be used with considerable sensitivity if they are to attain their objectives, and must be able to adapt to changing conditions. Each particular setting will have its own challenges, calling for a site-specific package of incentives and disincentives. The role of government in providing the policy framework is crucial (McNeely 1993).

After presenting examples of how local economic incentives can work, several strategies for generating economic benefits from the conservation and sustainable use of biodiversity are assessed. These include the development of non-timber forest products, ecotourism and private reserves.

13.5.3.1 Local economic incentives

McNeely (1988) describes several examples from Africa to illustrate how locally targeted economic incentives can work. In the Andohahela National Park, Madagascar, traditional plants are collected for food and medicinal purposes. To build stronger local support for the protected area, conservation efforts have repaired small irrigation canals, improved irrigation systems, and established tree nurseries. Nature protection agents have been recruited from local villages (Durbin and Ralambo 1992).

In Kasungu National Park, Malawi, local people have been given the right to harvest tree caterpillars and to establish beehives in exchange for curbing other uses that are incompatible with the objectives of the park. The per hectare profits from these enterprises are higher than those that subsistence farmers can obtain by growing maize, beans and groundnuts. Similar programmes have also been established in Nyeka National Park and Vwaza Game Reserve (Mkanda 1992).

Box 13.5-4: Elements of a new approach to integrated conservation-development projects.

- **Involve local people** in all aspects of project consultation, identification, design, implementation, and evaluation, including strategic as well as day-to-day management. Draw on indigenous knowledge and technologies. Foster local ownership of and commitment to projects, and stimulate the emergence of local leaders and organizations to sustain project activities.
- **Clearly define project objectives** in ecological as well as socioeconomic terms. Identify the various social, economic, political and scientific interests that need to be reconciled (i.e. the trade-offs) in order for these project objectives to be realized.
- **Develop social, economic and ecological criteria for project site selection.** Be prepared to carry out extensive pre-feasibility work prior to final site selection. Recognize that little can be achieved without *strong local political commitment* to project objectives and the existence of an *adequate policy and legal framework*.
- **Mobilize a wide array of human and organizational resources.** Engage and encourage collaboration among NGOs, universities, and government agencies. Be prepared to support the strengthening or reorientating of NGOs to improve their effectiveness. Invest heavily in training people.
- **Carry out projects in a spirit of applied research and adaptive learning,** moving often between the drawing board and field testing, making adequate provision for the analysis and communication of results. Involve professional researchers. Explicitly identify the hypotheses that projects are exploring. Acknowledge and learn from failures. Disseminate findings on a timely basis and share information among projects.
- **Conduct extensive ecological and socio-economic baseline studies** to (1) understand local systems, including their external linkages and dependencies, and (2) provide a basis for monitoring changes in key variables during project implementation.
- **Develop new quantitative and qualitative techniques and indices for monitoring and evaluation** (including participatory evaluations) to measure progress against project objectives, to guide project management, and to assess progress toward *sustainability* once external project support is withdrawn.
- **Assess the biodiversity impact of all investments and project interventions designed to generate local economic incentives for conservation.** Ensure an adequate balance between positive incentives (investments in social and economic development) and negative incentives (policing and enforcement) for conservation. Pay attention to *who* benefits, *how* they benefit, and *how much* they benefit from project development activities.

Source: Adapted from Wells (1995).

In Mount Kulal Biosphere Reserve, Kenya, incentives developed in consultation with local pastoralists include: legally registering tribal rangelands; water-resource development subsidies; banking facilities as a savings alternative to cattle; providing security against cattle raids by other tribes; conservation education; employment in protected areas; and income from tourism.

In the Cross River National Park, Nigeria, funds are being established to encourage local people to participate in park protection and management. A revolving credit fund will mitigate the effects of credit rationing on neighbouring farmers, providing they invest in activities that are supportive of the park. A crop-loss compensation fund will compensate farmers for damage done by species such as elephants that are protected by the park (Caldecott 1992).

Some of the most innovative uses of economic

incentives come from South Africa, where different agreements have been reached with people surrounding protected areas. These agreements include profit sharing, resource utilization, the preservation of traditional ceremonies, and the creation of local employment. Proceeds from the lease of a tourist lodge in the Mthethomusha Game Reserve are paid into a trust fund to be used for community projects selected by tribal authorities. In Richtersveld National Park, the land on which the park lies is owned and occupied by a Nama community that has leased it to the government but has retained rights to graze an agreed number of livestock and to the controlled harvesting of natural products. The lease funds are deposited into a fund, with trustees appointed by the community (Anderson 1992).

In Namibia, game populations have been conserved by giving ownership rights to ranchers, thus providing

landowners with a financial incentive to protect the animals. Prospective hunters negotiate fees directly with the landowners. As a result of this simple incentive, some protected species have now increased in numbers, and breeding stock are being sold to landowners at subsidized prices. This approach has proved successful with black rhinoceros, which ranchers perceive as a prestigious animal to have on their property (Joubert 1992).

Some African countries are considering ways of providing economic incentives to private enterprises to conserve biodiversity. In Zambia, for example, private enterprise has taken over the management of Kasanka National Park. About 100 local people have been hired and community projects have been launched to offset local peoples' lost access in the park to fish and meat (Farmer 1992). The South African National Heritage Programme encourages farmers to register their land as heritage sites. Sponsored by a French company, the programme provides management advice and financial support to help owners maintain or enhance the sites. Over 150 sites, some of outstanding conservation value, had been registered by 1992 (Cohen 1992).

13.5.3.2 *Conserving and using non-timber forest products*

Considerable debate has developed over the possibilities and limits of profitable and sustainable harvesting of non-timber forest products as an economic incentive for conservation (Coradin and Lleras 1988; Nepstad and Schwartzman 1992; Plotkin and Famolare 1992; Clay and Clement 1993; Corry 1993; Clay 1994). Critics argue principally that:

1. subsidies are virtually always necessary for non-timber forest products to compete in international markets; and
2. unrealistic expectations have been created in local communities regarding potential economic benefits from marketing non-timber forest products, leading to disappointment and mistrust (Coradin and Lleras 1988; Corry 1993).

Proponents respond by arguing that:

1. subsidies may not be needed when effective marketing strategies are used to emphasize the rarity, authenticity and social contributions that characterize such products; and
2. such programmes should be judged, at least initially, on broad grounds since they provide communities with income, access to technologies, training and management skills, and the value of a standing forest (Plotkin and Famolare 1992; Clay 1994).

However, the extent to which the marketing of non-timber forest products contributes to biodiversity conservation is far from clear.

Exploitation of marketable biological products includes edible fruits, oils, latex, fibres, medicines, bushmeat, hunting trophies, construction materials, and so on (see, for example, de Beer and McDermott 1989; Falconer 1990). But the economic value of a sustainable flow of non-timber forest products is very difficult to establish (Godoy and Bawa 1993). de Beer and McDermott (1989) estimated that exports of non-timber forest products from Thailand were valued at approximately US\$15 million in 1982 (see Figure 13.5-1). Reviews of studies world-wide have suggested mean yearly market values of about US\$50 million (Godoy *et al.* 1993) and US\$70 million (Lampietti and Dixon 1995).

In economic terms, the attractiveness of harvesting these products commercially depends on their opportunity costs, i.e. the economic benefits from the next-best alternative. In the case of tropical forests, this is often logging and/or conversion to agriculture. But sustainable exploitation limits for biological resources are difficult to determine in ecological terms and difficult to regulate without enforceable local access and ownership rights. Without soundly based and enforceable harvesting limits, local communities may not be able to derive increased economic benefits from – or perceive any incentive for – conservation or sustainable use of non-timber forest products (see Box 13.5-5).

Extractive reserves managed by local communities in Brazil are often promoted as an effective way of sustainably harvesting non-timber forest products. But the applicability of this approach depends on many different factors. These include the political power of the rubber-tappers' union, the interests of local cattle ranchers, the market demand for rubber products, the abilities of communities to get their products to market, and so on (Browder 1992). Until these and other influences are understood, it will be unclear whether the use of non-timber forest products will be economically sustainable. In isolation, a local community may be able to meet their economic needs and aspirations; but when national or international markets or politics intervene, they may no longer be able to do so (Robinson 1993).

13.5.3.3 *Ecotourism*

Ecotourism has a substantial and well-publicized potential to boost local and national economies, provide long-term local employment, and generate new funds for conservation – all without damaging biodiversity (Boo 1990; Lindberg and Hawkins 1993; Brandon 1995a). But excessive visitation continues to cause serious damage to biologically diverse and fragile areas, and ecotourism's financial and economic potential has remained largely unrealized – except by commercial travel operators. Particularly in developing countries, there is an acute need for careful analysis of ecotourism to identify appropriate policies that can:

Figure 13.5-1: Exports of non-timber forest products from Thailand in 1982. (Source: DeBeer and McDermott 1989.)

1. capture a greater proportion of ecotourism’s economic benefits locally and nationally;
2. regulate visitors’ adverse environmental and cultural impacts; and
3. provide additional funds for biodiversity conservation.

Developing countries’ governments have been reluctant to invest adequately in the management and protection of the natural and cultural assets (such as parks and reserves) that attract ecotourists. Often, so little of the economic value of ecotourism is captured by the host country that these assets are perceived as being of inconsequential value, and there is little political support for financing their management (Wells 1993).

But there are several countries that are extremely popular ecotourism destinations where this is clearly not the case. In Nepal, for example, simple calculations show that the total economic benefits attributable to parks-related ecotourism are significantly greater than the direct costs incurred by the government in maintaining the protected area network. Despite the greater overall benefits to parks from ecotourism, the direct cost of park protection and management – i.e. the conservation agency’s budget – is more than ten times larger than the actual amounts collected as park entry fees. The government’s neglect of Nepal’s parks may therefore be based on the illogical view

Box 13.5-5 Rattan cultivation in Indonesia.

Rattans are one of the most important forest products in Southeast Asia. They have been used for centuries in binding, basketry and weaving, and are now a major source of cash income (de Beer and McDermott 1989). Managed rattan harvesting is an attractive candidate in forest conservation and local development efforts because these plants have a wide range of traditional uses, are an important source of cash income, and have little or no effect on other forest flora and fauna when harvested. However, wild supplies are likely to be exhausted without management.

The forests of Kerinci-Seblat National Park, Indonesia contain about US\$15.80 unprocessed *Calamus exilis* rattans per hectare, based on 1990 market prices. Collectors report that these plants can be harvested annually once they have reached three years of age. The potential value of sustained-yield harvesting is about US\$5 per hectare per year. This is very low in comparison with the earnings from cash crops such as cinnamon and coffee, which can earn farmers about US\$1000 per hectare per year on cleared forest land. But as a source of wages, rattan collection, at US\$1.50 per day, is more attractive than general agricultural work, at \$1 per day.

These data seem to confirm that rattan is currently being exploited at a rate many times greater than it can replenish itself. But sustainable rattan harvesting could be made more attractive to local communities by improving cane processing techniques (for example, the use of simple, inexpensive machinery to remove silica cane sheaths) and thereby improved product marketing. Rattan handicraft and basket-making already provide more than 70 families with their main cash income. Managed rattan gathering may be an important component in conserving Kerinci-Seblat National Park.

that the country’s parks are a money-losing enterprise (Wells 1993). Similar studies would almost certainly reach similar conclusions in Costa Rica, Ecuador, Kenya, Tanzania and several Caribbean islands.

Although developing-country governments often assert that the objective of tourism is to maximize foreign exchange earnings, surprisingly little consideration has been given to the question of whether government revenues from tourism could or should be substantially increased through higher fees and charges. At least part of any increase in revenues should logically be reinvested in the

conservation and management of the natural and cultural assets that attract tourists, and upon which the sustainability of the industry and its accompanying foreign exchange benefits presumably depend (Wells 1993). With a few notable exceptions, governments appear reluctant to increase visitor fees substantially, perhaps not wishing to risk deterring some visitors and thereby reducing the total number of tourists.

But maximizing tourist numbers may not be the best strategy. Depending on the demand for tourist attractions, total revenues may in fact be maximized by reducing tourist numbers and increasing their per-capita expenditures (Lindberg 1991). Simple, low-cost, survey-based research studies can be used to estimate demand curves for parks-based tourism and thereby either justify or help to eliminate fears of losing tourist revenues through higher charges (Lindberg 1991; Tobias and Mendelsohn 1991).

The unrealized potential of ecotourism to contribute to biodiversity conservation or economic development in many developing countries may be linked to some key policy issues:

1. The value of protected area tourism has been substantially underestimated by governments and a less-than-optimal investment made in park management.
2. Very little of the economic value of ecotourism is being appropriated by the host countries, either in terms of public sector revenues or in local employment opportunities (Wells 1993).

The examples that follow illustrate how ecotourism can act as an effective economic incentive for conservation in a variety of circumstances.

Ecotourism in the Caribbean. Tourism is the number-one industry for most Caribbean states. Spending by tourists contributes 80% of the gross domestic product of the British Virgin Islands and Antigua/Barbuda, and 50% or more in Anguilla, the Cayman Islands, the Bahamas, St Kitts and Nevis, and the US Virgin Islands (Blumenstein 1993). Most Caribbean states have established protected areas to conserve biodiversity. In 1988, there were 135 legally established protected areas in the Greater Caribbean Basin. But increasing tourism use is imposing considerable pressure on these parks and reserves, most of which have modest budgets. Are there ways to combine effective protected-area management with increased economic activity, in this case tourism? Dixon and van't Hof (1995) describe examples suggesting that there are.

The Virgin Islands National Park (VINP) is well funded by Caribbean standards, one of the benefits of being part of the US National Park System. The 25 000 acre VINP has underwater snorkelling trails, numerous beaches, bays and cays, mangrove areas, and the Virgin Island Biosphere

Reserve Center. The park is popular with hotel visitors, and yacht and cruise ship visitors. A pioneering study found that 450 000 VINP visitor-days in 1980 generated US\$23.4 million for the island economy, while annual management costs were only about US\$2 million (Posner 1981). More recent data confirm the growing importance of the park to the local economy, with the number of recreational visits almost doubling to 800 000 by 1988, and luxury hotels being constructed within reach of the park. Such levels of tourism have had some negative environmental impacts on VINP, with boat groundings and anchor damage becoming an increasing problem. But the park has been awarded monetary damages as a result of lawsuits over cruise ship damage of the park's reefs. Overall, effective, well-funded park management has permitted increased levels of tourism to provide dramatic local economic benefits (Dixon and van't Hof 1995).

The Bonaire Marine Park was established in 1979 but immediately ran into financial difficulties. The international diving media opposed the introduction of user fees, and government funds for management were soon exhausted. Local dive operators then worked as volunteers for several years to provide informal management. But in the early 1990s, growing realization of the need to protect coral reef ecosystems resulted in the Dutch Government's providing a grant and the Bonaire government approved an annual US\$10 admission fee to the park. These fees raised US\$170 000 in 1992, the first year, sufficient to meet the park's operating and maintenance costs. These fees are being used only to support education and research programmes, to improve mooring systems, and to enforce park regulations. Enthusiastic reporting by leading diving magazines in the United States has since led to rapid growth in the number of dive visitors. Use of the Bonaire Marine Park now appears to be approaching its carrying capacity. Additional monitoring is under way to explore whether this capacity can be increased through better management and diver education. Diver fees should be adequate to meet future park management costs (Scura and van't Hof 1993).

Other Caribbean marine parks have introduced user fees to help pay for improved management. The Saba Marine Park charges \$2 per dive, plus mooring/anchorage fees averaging US\$2 to US\$3 per person. The Hol Chan Marine Reserve in Belize has obtained the support of local communities and is charging snorkellers and divers a modest US\$1.50 user fee. Several other marine parks in the region are now considering similar fees to help protect their marine resources, thus helping to meet both economic and ecological goals (Dixon and van't Hof 1995).

Community-based ecotourism. Capirona in Ecuador is an indigenous Quechua community of 24 families that has developed its own small-scale tourism industry. Most of

the community raise their own food in garden clearings. They also hunt, fish and grow some cash crops. Many of the residents had experience working as guides and cooks in a nearby town that catered to tourists visiting Ecuadorian rain forests. In 1989, they decided to market their town and create a small tourist industry using their own resources. The community felt that tourism could be a viable economic and culturally sensitive activity, but only if they controlled the project themselves and if the whole community benefited. A small guest-house was built near the village centre, where visitors can stay for up to six days. The people of Capirona share their traditions through a cultural exchange programme. Local guides show tourists the native uses of forest plants and animals, and describe the realities and challenges of their everyday lives. In addition to the income generated for guides and cooks, tourism revenues have also financed projects at the community school and in health care (Brandon 1995a).

This enterprise benefited from effective marketing by regional and national Indian organizations and by travel agents in Quito. The Federation of Indian Organizations of the Napo (FOIN) helped train community members in taking care of visitors and managing a small business. FOIN also found an Indian botanist to help mark out trails and label trees with scientific, Spanish and Indian names. The number of visitors has expanded from 50 in 1989 to 300 by 1994. Residents of Capirona are now helping other communities launch similar projects (Brandon 1995a).

This entire enterprise was initiated and financed by the community. It is managed by local people for the community's benefit. Tourism diversifies the local economic base and supplements local incomes. Local people feel they have improved their own situation, and helped protect their own culture. But the community is not dependent on tourism, and remains free to choose whether, or how, to continue. The Capirona case shows the importance of national organizations in providing training and technical assistance, and shows how communities adopt practices that have been demonstrated to work well for their neighbours (Brandon 1995a).

Ecotourism in conservation areas. The 4600 km² Annapurna Conservation Area, Nepal may be the most geographically and culturally diverse protected area in the world. About 40 000 people of diverse ethnic backgrounds inhabit the area, where agriculture and trade have flourished for hundreds of years. Most of these people are poor rural farmers. Tourism has grown rapidly and more than 40 000 foreign trekkers now visit the area each year. A proliferation of small tea shops and lodges has developed in villages to cater to these visitors. During the last two decades, large areas of forested land have been cleared to provide fuelwood for use in cooking and heating for visitors. Expanding agriculture, water pollution, poor

sanitation, and littering on trekking routes have all accelerated (Bunting *et al.* 1991).

A six-month survey of local villagers revealed that establishment of a national park would meet resistance and hostility, a reaction amply justified by the history of many of Nepal's other protected areas. An alternative was clearly needed (Sherpa *et al.* 1986). Eventually, the multiple-use Annapurna Conservation Area was established in 1986 (see Figure 13.5-2). Its programme specifically allows hunting, collection of forest products, use of visitor fees for local development, and the delegation of management authority to the village level. Management of the Annapurna Conservation Area Project (ACAP) was delegated to the King Mahendra Trust for Nature Conservation, Nepal's pre-eminent non-governmental organization.

The project objective is to help the inhabitants maintain control over their environment. Activities have included community development, forest management, conservation education, research and training. High priority was given to reducing the environmental effects of visiting trekkers and to increasing the local economic benefits from tourism. Training courses for lodge owners helped upgrade the quality of service, standardize menus and prices, and improve standards of sanitation and waste disposal. Lodges and expeditions were required to use kerosene inside the Conservation Area, with fuelwood use permitted for subsistence only. In a revival of a traditional organization structure, forest management committees have been established to enforce regulations (e.g. by fining poachers and controlling timber cutting). The government does not provide any staff or funds to manage this protected area.

ACAP has made significant progress in integrating tourism, local economic development and protected area management where local people are involved in both tourism and management of the protected area, and where the visitor entry fees are reinvested locally. Visitor entry fees generate about 4 million rupees (US\$160 000) annually for ACAP, and the project is approaching financial self-sufficiency (Wells 1993).

13.5.3.4 Private reserves and private land leasing

In many countries, privately or communally owned lands have tremendous biodiversity value. While protected area strategies are typically assumed to be synonymous with public land ownership and management, privately and communally owned lands can also be managed simultaneously managed to conserve biodiversity and to generate local economic benefits. Privately owned reserves and leasing of private lands for publicly managed conservation areas are two examples.

Privately owned reserves show how the private sector can be incorporated into a strategy of sustainable development and conservation. The number of privately owned reserves in Latin America has increased

substantially in the last ten years. Africa, on the other hand, has a long history of private lands used for tourism and sports hunting. A survey of private reserves in Latin America and Africa by Alderman (1994) explored the role of these reserves as a tool for conservation, development and education. This survey revealed the following:

- Private reserves generate substantial local employment, particularly those reserves that cater to ecotourism. For each 1000 visitor nights, between 32 and 40 employee-months were generated. This provides some empirical response to criticisms that nature tourism creates few jobs, and often not from local communities.
- While the costs of establishing private reserves are relatively high and depend largely on foreign investments, 75% of the reserves are either owned by nationals or are owned by partnerships between foreigners and locals. This depends on local laws. Costa Rica and Ecuador, for example, are atypical in that they allow foreigners to own land. Both countries have a large number of private reserves.
- Lack of government co-operation was reported as a problem by 63% of the reserves. The establishment of private reserves in some countries is hindered by laws that require landowners to clear forest lands rather than protect natural ecosystems.

Figure 13.5-2: Land-use areas in the Annapurna Conservation Area, Nepal. (Source: McNeely *et al.* 1990.)

- About a third of the reserves have an agreement with government or private institutions to restrict future development of the land, in exchange for incentives such as lower taxes or commitments on the part of government not to appropriate the land. Such incentives can help make private reserves an attractive alternative to destructive uses of the land.
- Ecological importance is not the same as economic viability. Reserves with the highest ecological value are not necessarily the ones that do well financially. The economic success of private reserves is more dependent on factors such as accessibility, management, and the prevailing political situation.
- Economies of scale provide an incentive for private reserves to maximize their tourist visitation rates, yet this may stress the ecosystems contained within the reserves.
- Many private reserves indicated that they would like to implement habitat management plans, but did not have the resources or expertise to do so. This is clearly an area where conservation groups could become more involved in providing technical assistance. This need not be viewed as a subsidy to the private sector, but rather as an opportunity to develop mutually beneficial relationships.

Certain customary landowners in the Pacific island nation of Vanuatu have, in principle, recently agreed to lease their forested land to the government in order to establish the Erromango Kauri Protected Area. This agreement concluded a lengthy process of socioeconomic assessment and negotiation that explored different options for compensating the landowners. With financial support from the European Union, the Government of Vanuatu now plans to lease the land at the rate of US\$10 per hectare per year, initially for a five-year trial period. In return, landowners will not allow logging to take place in the protected area. If this arrangement is extended beyond the first five years, funding will be sought to establish a trust fund to meet the future lease payments (Tacconi and Bennett 1995).

The use of participatory rural appraisal techniques revealed that the area proposed for protection was only of very limited subsistence use to local villagers, being too far from their residences. But the lease agreement (drafted in the village of Happy Land together with the landowners, village chief, the representative of the youth, and the representative of the women) allows limited use of the protected area site for subsistence purposes. These activities would be regulated by a protected-area management committee essentially controlled by the customary landowners (Tacconi and Bennett 1995).

Attempts were made to simulate the landowners' economic choices. Discounting estimated logging royalties at 4%, it was found, would give returns comparable with the likely terms of the lease agreement, although the range and uncertainties inherent in the data were substantial. Other options were also discussed with the landowners. The government could, for example, with donor support, provide financial and technical support to develop income-generating activities in exchange for an undertaking by the landowners to protect the forest. The landowners pointed out that economic development would be constrained by the lack of a road and access to markets. Furthermore, the landowners preferred the steady income from a lease to the uncertainty of a comparatively risky income-generating project. No viable economic activity yielding short-term benefits could be identified for such a project. Therefore, the landowners opted for the lease agreement (Tacconi and Bennett 1995).

13.5.4 Conclusion

Locally-based conservation is, in some ways, a reaffirmation of traditional ways of thinking about resources and the natural world. As Western (1994) notes, the past is in many ways the future:

If conservation is to become embedded in our daily activities, nature and society must be intimately linked in our minds. This is a radical departure from the Western view of the separateness of Man and Nature – one that rekindles a holistic, ancestral way of thinking about our species in relation to the rest of the natural world. Research, knowledge and education will have a central role to play in the conceptual shift if we work on the premise that rural communities have as much to teach others as they have to learn about how to live in a more integrated world.

This doesn't deny the importance of viewing sustainability in global terms. But, virtually all approaches to biodiversity management cross important, locally defined socioeconomic terrain. Therefore, using social and economic incentives and tools that enable those people living closest to the resource to benefit equitably from the protection and sustainable use of biodiversity is indispensable. There is still much to learn about local socioeconomic factors in biodiversity management. This learning, and more importantly its incorporation into daily biodiversity management, is one of the most difficult and challenging aspects of conserving biodiversity and using it more sustainably.

13.6 Legal measures for sustainable use and protection of biodiversity

13.6.1 Introduction

Most nations are parties to one or more international treaties of relevance to biodiversity. All are required to take action at the national level to implement their obligations. In particular, the Convention on Biological Diversity – the only global biodiversity-related treaty to take a comprehensive approach – places its main emphasis on action at the national level. Legal measures are critical tools for countries seeking to maintain their diversity, regardless of their status as parties or non-parties to international agreements (de Klemm and Shine 1994).

Chapter 13.6 considers the legal measures that can be used to regulate activities that have adverse impacts on biodiversity; to create the legal basis for implementing technical, social and economic incentives or voluntary measures to sustainably manage and protect biodiversity; and to develop combinations of regulatory and voluntary approaches. Legal measures are considered in the context of traditional legal systems and modern legal systems used at national and international levels. The chapter concludes with a brief look at the most relevant global treaties concerned with biodiversity.

Conservation often requires that the activities of people be regulated or directed. This may be achieved by legal dictates or by incentives that rely more on voluntary measures. Law has an essential role to play in both cases.

Laws regulating the use of living resources have principally been concerned with protecting the interests of humans and societies, and not with the inherent 'rights' or interests of nature itself. Pollution control legislation has as a priority objective the protection of human health, not biodiversity. Protected areas created by national governments were initially established more for public enjoyment than because of their richness in species, although the motivation of traditional societies, which created some of the earliest forms of protected areas, was varied.

As a consensus evolved around the need to preserve wild species and areas for their intrinsic value and for future generations, so did the number of laws enacted to preserve elements of biodiversity. However, constraints resulting from those command and control regulatory measures are often still perceived as illegitimate; nature from time immemorial has been considered as a free gift, especially in Western societies (although some restrictions such as

hunting licences may be a well-accepted practice in many developed and developing countries). Its destruction was not considered to affect any recognized human interest. Restrictions established for its conservation, moreover, impinge on rights that are often enshrined in constitutional provisions, such as free enterprise, property ownership and economic development. As a result, regulatory conservation measures are often unpopular and ineffective, yet these are still almost universally relied upon to protect species and ecosystems. In some traditional cultures, however, regulatory measures have been mutually agreed upon and mutually enforced by members of the community.

There is consequently a need for more legal incentives that promote voluntary action to complement or replace coercive legal restrictions. This was recognized in Article 11 of the Convention on Biological Diversity (CBD), which calls upon each contracting party to adopt incentive measures for the conservation and sustainable use of biodiversity. The need to achieve an appropriate balance between regulatory and incentive-based legal approaches is therefore even more urgent. The primary means of establishing regulation and creating economic and other incentives is through the legislative process. Legislation is essential for:

- conferring jurisdiction and powers on public bodies and local communities for conservation;
- instructing public bodies to carry out conservation measures;
- establishing and enforcing procedures (such as EIAs);
- providing for public participation;
- permitting NGOs or other organizations to sue in cases of non-compliance;
- providing incentives for conservation and disincentives to destruction;
- providing a legal basis for conservation contracts such as easements and management agreements, and for the equitable sharing of benefits; and
- implementing obligations under international agreements.

13.6.2 Customary and traditional legal measures

Long before national governments began to pass legislation and regulations concerning the conservation of biodiversity and the use of biological resources, traditional communities around the world already possessed a varied and complex store of customary law dealing with the same issues. The survival of these communities depended upon effective systems of husbanding biological resources. Traditional knowledge of and techniques for using biological resources may therefore provide valuable information ranging from effective management techniques to the pharmaceutical or agricultural applications of particular species. While many

traditional cultures have disappeared or been assimilated into dominant societies and economies, others continue to exist, albeit in varying degrees. In some cases, traditional legal systems used to manage biological resources in agriculture, forestry, fisheries and hunting (see 13.3 for traditional management practices) are still effective. And traditional legal systems may have features from which modern legal systems might benefit.

The Convention on Biological Diversity recognizes the links between indigenous and local communities embodying traditional life-styles and the conservation and sustainable use of biodiversity. The Convention – Article 8(j) – calls upon each contracting party to respect, preserve and maintain the knowledge, innovations and practices of these communities relevant to the sustainable use and conservation of biodiversity. It also encourages their wider application and the equitable sharing of benefits from their use.

Many remaining traditional cultural groups occupy areas of unusually high biodiversity, including the Amazon and Congo Basins, the interior of New Guinea, Borneo and other Southeast Asian islands, parts of Australia, Mexico and Central America, and many mountain areas in the Andes, Himalayas and elsewhere. Traditional cultures are not only often contiguous with the planet's remaining areas of high wild biodiversity; they are also custodians of a great deal of the planet's agricultural genetic diversity, in the form of local crop and livestock varieties. Customary law governing biodiversity is thus as complex and varied as the resources it seeks to protect.

13.6.2.1 The nature of customary law

While customary laws and legal systems vary from culture to culture, they generally share a number of characteristics that set them apart from the 'modern' legal orders that govern – at least in theory – behaviour in national legal and political systems. Most customary societies are structured by a single, integrated hierarchy of law, behaviour and authority – the same web of rules, authority and authority figures governs all aspects of life, from tenure to marriage, from spiritual matters to hunting restrictions.

Customary laws concerning biotic resources – despite their many variations – can often be found where land, water and their resources support a broad array of seasonally staggered activities. Some combination of long-rotation polyculture cultivation (swidden), hunting, fishing, herding and the collection of forest and marine products will tend to dominate over sedentary, intensive agriculture or the intensive exploitation of a few species for the market.

Some common characteristics of customary laws are that:

- Land, water territories, and their biotic resources have socio-religious significance, are closely

connected to the identity of the group, and cannot easily be separated from matters of kinship, authority and leadership, modes of subsistence, ritual and the supernatural.

- Individual, heritable rights in land (or water territories) exist, but most individual rights are either rights of use subsidiary to a superior group right, or rights to particular resources, such as tree or animal species, or rights to harvest a particular cultivated plot. Thus, land tenure and resources tenure are not necessarily the same, and one parcel of land is often encumbered with a variety of rights held by different persons and groups.
- Unworked land or waters are, for the most part, as encumbered by rights as individual garden plots. Rarely is any part of the land- and seascape in which the community lives considered 'empty'.
- Rights in land, waters, and their resources are rarely recorded in maps or written records, with the exception of ownership marks placed on trees and other discrete, individually owned resources. Borders are determined on the basis of natural features, such as rivers, and by mutual unwritten understandings.
- Limits are frequently set on the exploitation of particular resources – often regulated on a seasonal basis, and some areas and resources are often put completely off limits, as in the case of India's 'sacred groves'. There is little conceptual or practical separation, however, between concepts of 'use' and 'conservation' of living resources.

All of these generalizations have exceptions, and few societies now live wholly within a customary system. Nevertheless, even as many people and institutions throughout the world grapple with the task of slowing biodiversity loss – and finding the legal tools to do so – there is still a great deal to learn from systems of customary law.

People in modern societies, by contrast, live in and are governed by a variety of hierarchies, each with its own set of norms and expectations. In one's home, car, workplace or place of worship, a different set of norms and laws – customary and otherwise – apply, and behaviour must be adjusted accordingly.

The hierarchies a person lives under are integrated and interrelated in varying degrees. Related to this is the distinction drawn by Dasmann between 'ecosystem people' and 'biosphere people' (Dasmann 1988). Ecosystem people are those, in Gadgil's (1993) formulation, who 'obtain most of the resources they use from a restricted catchment either

by gathering or through low-input agriculture and animal husbandry'. Biosphere people are those who 'participate in the global market economy which gives them access to resources from all over the earth'. To these two groups, Gadgil (1993) notes, must be added a third group of 'ecological refugees', most of whom are ecosystem people who have been deprived of their resource base. Indeed, Attali (1991) has argued that in the next century, biosphere people and ecological refugees will be the only remaining categories, which he terms 'rich nomads' and 'poor nomads'.

13.6.2.2 Examples of customary law and biodiversity

Existing interdependently with their immediate natural environment, traditional cultures have developed diverse and complex systems to regulate their members' uses of living resources. Following are just a few brief examples; thousands have been documented, and many thousands more are likely to exist, or have existed in the recent past.

In the mountains of Nepal, close to the tree line, the Sherpa people utilize a system called *shinga naua*, in which several men from a village are elected to protect the local forest. These traditional forest guards have the power to prevent cutting of protected forests, determine where trees may be cut, inspect firewood stocks in people's houses, and levy fines for transgressions (McNeely 1989).

In Thailand, traditional communities have evolved numerous methods of conserving local forests, including ancestral spirit and temple forests, and for forest patches conserved for watershed and soil protection. The customary laws that protect these forests are accepted by the community because they are part of the culture and because every village member has a role in enforcing them. Transgressions are dealt with through fines, penalties or in many cases through social pressures (Amornsanguansin, undated).

In Orissa and other tribal parts of India, a variety of customary restrictions in the past ensured that the forests were not over-exploited. They included restrictions confining exploitation to certain seasons, restrictions based on certain stages of a species' life-cycle, bans on cutting certain sacred species, limits on quantities to be exploited, and complete bans on harvesting from certain areas. Such traditions have, however, been substantially eroded (Fernandes 1988). Similarly, the Gorowa of Tanzania and the Gabra of Kenya protect ancient forest groves as sacred sites (Durning 1992).

In Papua New Guinea, customary land tenure systems specify who may use, inhabit, harvest, collect or hunt from the forests, as well as where, when and under what circumstances (Iamo 1992; Taylor 1994). State recognition of customary land and resource tenure systems is most developed in Papua New Guinea and a number of South Pacific island nations. Neighbouring Indonesia's Irian Jaya province, for example, possesses numerous traditional systems for regulating forest use, but traditional (*adat*) law is not recognized by national forestry law and policy (Barber

and Churchill 1987). In the dry zone areas of Sri Lanka, where paddy cultivation was carried out with the aid of rain water collected in tanks, a system regulated the distribution of irrigation water during periods of drought. During such periods, the area of land that could be harvested with the aid of the remaining water was determined for the entire village in proportion to their ownings of the entire paddy land.

No less common are customary law systems governing conservation and use of fisheries and other marine resources (Maragos 1992). In Indonesia's Molucca islands, the *sasi* system of customary restrictions on the harvest of various marine species ensures their survival (Zerner 1994). Throughout the Pacific islands, traditional systems of reef tenure and harvest management have long supported sustainable use and conservation (Simmonds 1992). And on Borneo's Kapuas River, traditional communities have developed a system for controlling the harvest of valuable red Asian arawana fish (Bailey 1990). In some parts of Sri Lanka, complex systems of rules governing the harvest of marine resources remain in place, for example the total ban on prawn harvesting during the breeding system in the Baticaloa lagoon.

13.6.2.3 Customary law in transition

Customary systems of resource management and resource law work best under low population densities, without significant external market involvements, with traditional technologies, and where traditional systems of authority – and authority figures – remain strong. Such conditions are becoming less common at the close of the twentieth century. Everywhere customary societies are breaking down as their natural resources are appropriated by governments, corporations and migrants; the seemingly inevitable assimilation into the global economy and culture is felt in virtually every corner of the planet.

Any number of well-established civilizations in human history have vanished because they could not adapt to the pressures of rapid change. Never has change been as rapid as it is at present, and it seems inevitable that many traditional cultures, their knowledge, and their systems of customary law, are bound to vanish before the close of the next century, some well before that. Yet, there are some traditional cultures that have been able to adapt and accommodate the pressures and opportunities of modernity, and in doing so maintain modified systems of customary law that continue to protect biodiversity. Some national legal systems, such as that of Papua New Guinea, have also expressly recognized the legitimacy of traditional legal systems involving resource management, even as those traditional systems strive to adapt to changing circumstances (Lynch 1992).

13.6.3 National legislation

All countries have formal legal systems and nearly all have legislation, policies and legal procedures that govern the

protection, use and management of natural resources, including living resources. These measures vary widely among countries and often within countries where jurisdiction or authority over natural resources is shared with state/provincial and local governments. There are, however, broad categories of regulatory and non-regulatory legal measures to support the sustainable use and protection of biodiversity.

While leaving the details to individual contracting parties, the Convention on Biological Diversity nevertheless calls upon parties to take many of the general types of actions noted here. For example, Article 8(k) stresses the need to develop legislation or other regulatory measures for the protection of threatened species and populations. Without pre-judging the choice of action, cross-references to the convention will show the range of tools currently in use addressing the particular provision's concern.

13.6.3.1 Regulatory measures

Subject to any limitations established by constitutions, states have 'police powers' to control human activities in the general interest. Under these powers, laws and regulations may be enacted to prohibit or restrict specified activities, authorize them subject to permit, or require prior notification of proposed activities or projects. To date, these powers have mostly been used in relation to conservation to protect particular species or areas and, more recently, certain habitat types or landscape features. The Convention on Biological Diversity recognizes the importance of management or regulation at this level. The convention calls upon each contracting party to identify and monitor processes or activities likely to have significant adverse impacts on biodiversity (Article 7(c)) and to regulate or manage them (Article 8 (l)).

13.6.3.1.1 Species-orientated legal measures. Traditional hunting and fishing laws establish open and closed seasons, bag limits, prohibited taking methods and trade prohibitions or restrictions. Endangered species are protected by permanent closed seasons. However, hunting legislation is not usually applicable to non-game species, especially invertebrates and plants.

Species conservation laws have consequently been adopted by many countries in recent decades, and Article 8(k) calls upon countries 'to develop or maintain necessary legislation and/or other regulatory provisions for the protection of threatened species and populations'. These laws often contain long lists of protected species, including plants. Where they apply to non-game species, they can be difficult to enforce, especially for lesser-known species that may be difficult to identify except by a small number of specialists. They are, moreover, usually limited to taking and trade prohibitions, although a few go further.

The Spanish Act on the Conservation of Natural Areas and Wild Flora and Fauna (1989) requires the development of recovery plans for endangered species and habitat conservation plans for species listed as vulnerable to the alteration of their habitat. Plans are adopted by ministerial orders and include regulatory provisions binding on public agencies and the public. In Australia, the Commonwealth Endangered Species Protection Act (December 1992) contains requirements for federal endangered species recovery plans and threat abatement plans, and provides incentives for state and territorial governments to adopt similar plans. In Sri Lanka, the Fauna and Flora Protection Ordinance (as amended in 1993) relies on the precautionary principle and anyone seeking to alter critical habitat or 'take' protected species must prove that such actions will not harm the species.

The US Endangered Species Act (1973) requires that critical habitats of listed species be designated and that federal agencies ensure that actions authorized, funded or carried out by them are not likely to jeopardize the continued existence of these species or result in the destruction or adverse modification of their critical habitats. Federal agencies must conduct species conservation programmes and prepare species recovery plans.

In some jurisdictions (e.g. the United States and New South Wales, Australia), prohibitions on the taking of endangered species have been interpreted to include certain forms of habitat disturbance. This has resulted in a blurred distinction between species-based laws and area-based laws and, in the United States, has led to the restriction of development on both public and private land (Bradsen 1992). This interpretation with respect to private land was recently upheld in the US Supreme Court.

While species-based laws have had clear successes, they also have shortcomings. Laws that depend on substantial scientific proof of endangered conservation status and a concentration of financial resources on the recovery of a small number of species may not be suitable in many countries where both information and financial resources are limited. Unilateral actions to protect migratory species can also be ineffective when other countries fail to protect those species when they are within their jurisdiction, a problem that led to the Convention on Migratory Species.

13.6.3.1.2 Regulating use of protected areas. Within these areas, most activities are prohibited or restricted to ensure the long-lasting conservation of the ecosystems concerned. The continued existence of protected areas cannot be fully guaranteed by law since subsequent legislation may abolish a park or reserve. The disestablishment of a protected area may, however, be made more difficult than its establishment by the imposition of particular procedural constraints. For example, in New South Wales, Australia, an Act of Parliament is required to revoke a national parks designation.

The integrity of a protected area may be achieved through public ownership or regulatory measures. Under the former, the state or land-holding agency may prohibit or restrict activities by third parties on its lands. Further legislation is necessary to dedicate public lands exclusively to conservation, to bind government agencies to respect the integrity of the areas concerned, and to penalize illegal activities by third parties.

Legislation should facilitate government land acquisition for conservation purposes by instituting a right of pre-emption over land coming on the market, a right of compulsory purchase, and tax incentives for vendors. However, exclusive reliance on the public purchase of land for protected areas, as happens in several countries, has the obvious disadvantage of being expensive.

Regulatory measures applicable to both public and private lands are used elsewhere to establish protected areas, particularly in Europe where publicly owned land is scarce. While governments may restrict certain development activities by landowners in such areas, they cannot be forced to take additional positive measures to protect biodiversity.

Beyond the boundaries of protected areas, damaging activities must also be regulated to conserve those areas effectively. Buffer zones, in which specified activities are prohibited or restricted, are frequently established for this purpose, but these are insufficient if harmful processes are carried out farther afield.

The management of protected areas and the determination of powers conferred on their managing bodies is also a matter for legislation. Centralized management is characteristic of countries where parks and reserves are established on public lands. Protected area directors are appointed by the national administration and local interests are usually not represented in park management, although this is changing in some countries such as Zimbabwe and Kenya (see also 13.3.5 and 13.5.2.5).

Decentralized management is more usual where protected areas are established on private or municipally owned land. Management boards aim to represent all interests concerned and are composed of government officials and representatives of local authorities, scientific institutions, conservation NGOs, landowners and local economic interests. In France and Italy, these boards are corporate bodies with legal powers.

Legislation must make it possible to establish different zones within protected areas and to lay down basic rules and activity limitations applicable to each zone. Alternatively, management bodies may be given the necessary powers to incorporate these restrictions into a binding management plan.

In a few countries, the development of management plans is mandatory. In Australia, such plans are adopted

after a formal procedure and public consultations, and are binding upon public agencies and the public. The participation of local communities in designing and implementing protected areas is an important component of most successfully managed areas, and more attention should be given to how this can be effectively stimulated through legal provisions.

13.6.3.1.3 *Other area-based legal conservation actions.* Other, more flexible conservation instruments of a regulatory nature have been developed in recent decades for use in particular circumstances. Wilderness areas are established on large tracts of public land where certain activities, such as road building and the use of motor vehicles are prohibited.

Conservation orders are administrative decisions regulating certain activities in specified areas, but do not amount to an official nature reserve designation. The prohibitions or restrictions may be adapted to the conservation requirements of each area. This system is particularly well developed in Denmark.

Under the British system of Sites of Special Scientific Interest (SSSIs), all sites designated as SSSIs by national conservation authorities have a unique legal status. Where an activity (e.g. construction) requires a permit, the relevant authority must take account of that designation when granting or refusing a permit. In respect to all other activities, including agriculture or forestry, owners are notified of ‘potentially damaging operations’ likely to damage the site’s fauna, flora or other features. A landowner cannot carry out any such operation without first notifying the conservation authority. The latter will usually seek a management agreement whereby the owner agrees to refrain from the proposed activity in return for a sum of money.

13.6.3.1.4 *Land-use planning legislation.* Land-use planning legislation has been enacted in many countries to protect economic, aesthetic and environmental values in rural and especially urban and suburban areas, although agriculture and forestry are widely exempted from land-use regulation. Certain planning systems are timidly evolving toward the better protection of natural areas. In Portugal, areas of particular ecological value or vulnerability (e.g. beaches, dunes, cliffs, estuaries, river beds, wetlands and mountain slopes) form part of the National Ecological Reserve and must be preserved by municipal land-use plans. All works and any destruction of vegetation cover are prohibited in those areas and forest exploitation and afforestation are subject to permits.

In many countries, land-use planning is the responsibility of local governments. There are two broad categories: comprehensive planning and environmental site planning. Comprehensive planning includes *anticipatory* mechanisms such as zoning to define appropriate land-uses and anticipate or direct certain types of development (McEvoy and Dietz 1977). Comprehensive land-use plans are

implemented through four basic instruments: (1) public acquisition, (2) public investment, (3) incentives and (4) regulation (see Figure 13.6-1).

Environmental site planning is a *reactive* approach that seeks to restrict or avoid adverse environmental impacts on a site-by-site basis by, for example, specifying where a septic field drain should be placed to avoid contaminating an adjacent waterway (Bickford 1991). Site planning relies principally on regulation. Cort (1995) analysed the effectiveness of various land-use planning initiatives in conserving habitat in a Florida county (see Table 13.6-1). She concluded that public acquisition of sensitive habitats was more effective than regulation.

13.6.3.1.5 *Nature parks and protected landscapes.* The legislation of an increasing number of countries provides for the creation of nature parks. Human activities are allowed within a park’s boundaries if they are compatible with its objectives. Nature parks are usually zoned, and regulated activities vary between zones. Conventional protected areas such as nature reserves may be included as specially protected zones within the park.

The legal regime of nature parks varies widely. Some countries have few regulatory constraints. Others, like Spain, have strict rules on agricultural practices. The cultivation of forage crops, artificial grasslands, and afforestation with exotic species may be prohibited, and other forms of intensive agriculture made subject to a permit. All changes to the water regime are prohibited.

The law should ensure that the administrative body responsible for the nature park is closely associated with the park’s management and that local inhabitants and interests are adequately represented. The powers of such

Table 13.6-1: Hectares conserved under recent land-use initiatives in Hillsborough County, Florida.

County intervention	Instrument	Hectares designated	Hectares conserved
Significant Wildlife Habitat	Regulatory	48 986 ^a	9.7
Upland Forest Density Bonus	Incentive	not specified	2
Acquisition of Sensitive Habitats	Voluntary purchase	18 108 ^b	5 383
Livestock Density Control	Regulatory	not specified	repealed

^a Between 1992 and 1994.
^b Between 1987 and 1993.
Adapted from Cort (1995).

bodies should be clearly defined to avoid jurisdictional conflicts with government departments or local authorities. The nature park concept has now developed beyond Europe to certain developing countries such as Mexico. Nature parks are well suited to implementing the UNESCO biosphere reserve model, as they promote biodiversity conservation while maintaining traditional activities, and may combine the use of voluntary measures with regulatory constraints.

13.6.3.1.6 Legal protection of representative habitat types. Denmark’s Protection of Nature Act (1992) prohibits alteration to heaths, marshes, moors, salt marshes, coastal meadows, humid permanent grasslands and dry grasslands. Similar prohibitions apply to lakes of more than 100 square metres and watercourses designated by the Minister for the Environment. These prohibitions apply to any change in land use, including those made for agricultural purposes.

Other countries establish a permit requirement for activities that damage specified natural habitat types, such as wetlands (several countries), mangroves (Brazil and Venezuela), sand dunes (Brazil), riparian vegetation (many countries), and caves (Austria, Hungary, northern Italy). Some laws also protect specific landscape features, such as hedgerows. Australia’s Endangered Species Act provides for the listing and protection of endangered biological communities, although none to date has been added to the relevant schedule of the Act. The Australian State of South Australia requires a permit for the clearing of any native

vegetation in its Native Vegetation Act of 1991. Applications for approval to clear vegetation must be accompanied by a native vegetation management plan. However, Schedule 1 of the Act delineates situations in which vegetation should not be cleared (e.g. unusually high levels of species diversity, erodibility, or potential for salinization).

The RAMSAR Convention is an international agreement intended to lead to the conservation of an international network of representative wetland ecosystems. Other international programmes, such as the World Heritage Convention and UNESCO’s Man and the Biosphere Reserve Programme, are also designed to stimulate countries to protect, within their borders, habitats that are representative of the world’s ecosystems.

13.6.3.1.7 Regulating processes and activities detrimental to biodiversity. Many processes and practices, such as agricultural chemical use or the introduction of species, can have widespread adverse impacts on biodiversity. Few of these processes, however, are regulated. Most regulatory approaches to conservation instead emphasize the restriction of certain activities within limited areas. Processes that are regulated most commonly include the use of pesticides and the introduction of species. New legislation on genetically modified organisms is aimed at the protection of humans, livestock and crops as well as biodiversity. Article 8(h) of the Convention on Biological Diversity encourages countries to control the

Figure 13.6-1: Comprehensive versus site planning for biodiversity conservation. (Adapted from Cort 1995.)

introduction of species that may threaten native ecosystems, habitats or species, while Article 8(g) calls upon countries to regulate the release of 'living modified organisms' likely to have adverse environmental or human health impacts.

Other activities now regulated are the use of trawls and drift-nets at sea, and open-air activities such as off-road driving, rock climbing and the construction of golf courses. Controls are usually introduced only after the damage caused by such activities has become unacceptable to public opinion, yet proposed restrictions almost invariably clash with vested interests.

Methods to identify and manage processes and activities that may cause serious damage to biodiversity must therefore be developed before they become too established. A legal concept underpinning the regulation of damaging processes appeared for the first time in the Australian State of Victoria's Flora and Fauna Guarantee Act (1985). That law lists a number of 'potentially threatening processes' for mandatory management. Listed processes include alteration to the natural flow regime of rivers, the use of lead shot in cartridges for the hunting of waterfowl, and the introduction of live fish into waters outside their natural range. The Australian Federal Endangered Species Protection Act (1992) requires the preparation of 'threat abatement plans' for 'key threatening processes'.

There are, of course, major practical problems in the enforcement of command and control regulation in large 'modern' societies with diverse structures of authority. This is vividly illustrated by the 'shoot, shovel and shut-up' philosophy that prevails amongst some landowners in the United States who find endangered species on their land (Mann and Plummer 1995). The problems of policing command and control regulation in such an environment are insuperable. This suggests that relying solely on command and control regulation, particularly where the ideology of private property is strong, is unlikely to work without incentives for landowners to undertake positive acts of management.

It should be noted that in some countries, constitutional restrictions can make regulatory approaches to biodiversity conservation difficult. One frequently occurring constitutional provision that may cause difficulty is a guarantee against deprivation, or acquisition, or taking of property without compensation. In the United States, for example, this has been interpreted to include not only physical appropriation of land, but also significant land-use restrictions imposed by legislation. In Australia, on the other hand, this broader interpretation appears to have been rejected (Farrier 1995). Under the constitution of Tuvalu, 'deprivation' of property is defined to include cases where property is made useless or valueless for the purposes for which it was originally used (Pulea and Farrier 1994a). In Kiribati, there are specific exceptions to the prohibition on

deprivations of property without compensation (Pulea and Farrier 1994b).

13.6.3.1.8 Regulating access to genetic resources. The Convention on Biological Diversity affirms the sovereign right of nations to regulate access to genetic resources, and many countries are now beginning to develop legislation and regulations to put that right into practice (Reid *et al.* 1995). The need to do so is becoming increasingly urgent, as advances in biotechnology increase the value of wild genetic resources and spur their collection by agents of the pharmaceutical and other industries (Reid *et al.* 1993).

There is little precedent, however, upon which to build legal regimes for genetic resources access. Contractual arrangements for 'biodiversity prospecting' in a number of countries are the most widespread legal arrangement governing access to genetic resources for commercial purposes, but are by their nature too narrow to effectively control those who are not parties to the contract (Laird 1993). And while all contracts must function within limits set by national laws, existing laws governing business practices, property rights and the like are not necessarily appropriate for the novel situations raised by commercial exploitation of genetic resources.

Genetic resource 'source' countries face a number of common issues in developing access regulation laws and policies. First, they must establish the rules by which those seeking to collect genetic resources may do so, including provisions governing where, when and how collection may be carried out, information that must be provided by the collector, steps that must be taken to obtain the informed consent of local communities in collection areas, and the like. Second, they must establish regulations on benefit sharing (e.g. royalties on future commercial applications) and technology co-operation (e.g. participation by local scientists) which at least specify minimum requirements in these areas. Regulations in these two areas might be very specific – spelling out mandatory royalty percentages, for example – or they might only set minimum standards, leaving parties to negotiate individual contracts within certain legislative limits. In either case, however, governments must establish or designate the institution that will serve as the regulatory authority, and develop its rules of procedure.

Few countries have as yet set genetic resources access legislation in place. Two early initiatives, however, illuminate the legislative issues that all 'source' countries are facing. First, the Philippines issued a Presidential Executive Order in May 1995 establishing a genetic resources access regulation regime. Second, a proposal for an Andean Regional regime on access to genetic resources has been developed under the mandate of the Andean Pact countries.

The Philippines Executive Order establishes a system with three basic elements:

1. a system of mandatory Research Agreements between collectors and the government containing minimum terms concerning the provision of information and samples, technology co-operation and benefit sharing;
2. an Inter-Agency Committee to consider, grant, monitor and enforce compliance with Research Agreements, as well as to co-ordinate further institutional, policy and technology development and
3. a requirement and minimum process standards for obtaining prior informed consent from local and indigenous communities where collection of materials is carried out.

Research Agreements are divided into two types, academic and commercial. Recognized Philippines academic and research institutions and government agencies, as well as intergovernmental institutions, are eligible for academic agreements, while all research and collection directly or indirectly intended for commercial purposes may take place only under a more stringent commercial agreement. All private persons and commercial firms, whether foreign or domestic, are legally presumed to have commercial motives (Government of the Philippines 1995).

The Andean Pact initiative, prepared with technical assistance from IUCN and the Peruvian Society for Environmental Law, would establish a Common Regime on Access to Genetic Resources for Pact countries (Bolivia, Colombia, Ecuador, Peru and Venezuela). The system put forward for discussion by IUCN and the Peruvian Society of Environmental Law (SPDA) in 1994 would establish common legislation for all Pact countries, to be carried out by their respective national governments. Two criteria are deemed central: prior informed consent, and the determination of mutually agreed terms between all entities concerned, one of which will always be the state.

Under the system, each country would appoint a Competent Authority charged with authorizing access in conformity with the norms of the Common Regime. Collectors of genetic resources would be required to obtain proof that such authorization had been obtained, in the form of a valid Certificate of Origin or Material Transfer Agreement. (The former is a document issued by the Competent Authority of a member state, certifying that access to the materials specified in the certificate has in fact been authorized. The latter refers to an agreement between a provider and recipient of genetic resources which establishes the mutually agreed terms between them.) While the system recognizes that each country's procedures for authorization will vary, it establishes that authorization is valid only when all procedural requirements have been met, sets out a common set of issues for which rules must be established system (e.g. third-party transfers of materials, obligations related to intellectual property rights, in-kind benefit-sharing, deposit of duplicates, etc.), and

mandates development of common administrative procedures for granting access in each member country. Within this framework, contractual access agreements are permitted, and each state is obliged to adopt measures to allow indigenous and local communities to enter into access agreements (IUCN/ELC and SPDA 1994).

While the current focus for developing access legislation is on genetic resource source countries, it is clear that recipient countries will also have to develop legislation to regulate the activities of researchers and commercial firms domiciled within their boundaries. Without this parallel development, source country legislation is likely to remain very difficult to enforce.

13.6.3.2 *Non-regulatory methods*

In the absence of regulatory measures, area-based conservation depends entirely on the will of the landowner, whether public or private. Even where appropriate incentives are provided, however, the means of protection available to private landowners are somewhat limited. Prohibitions on access to land may be difficult to enforce. Governments may expropriate land for public works. Protection disappears when the ownership of land changes, except when covenants or easements are in force.

13.6.3.2.1 Financial incentives. Disincentives to conservation, such as high land taxes on 'idle' land, should be ended as a first incentive measure, and fiscal or other incentives to develop natural habitats should be abolished. For example, federal legislation instituting the Coastal Barrier system in the United States prohibits all federal expenditure in listed undeveloped barrier islands.

As well, disincentives to destruction of natural resources should be introduced. Again in the United States, all federal subsidies have been abolished for landowners who drain wetlands for agricultural production, pursuant to the Farm Act (1985).

Some jurisdictions grant tax reductions or exemptions to landowners who maintain natural areas, provided that they comply with management guidelines. Land donated for conservation purposes may be exempted from land-transfer tax, and its value deducted from taxable income. The United Kingdom exempts land of outstanding natural value from death duties if the heirs manage the estate according to a management plan approved by the conservation authority. Direct grants to landowners may also be made for the acquisition and management of land for conservation.

13.6.3.2.2 Covenants. A covenant is a legal instrument irrevocably binding a landowner to certain land-use restrictions on a specific piece of land. The owner, who may continue to occupy the land, receives no payments other than possible land tax reductions. The obligation runs with the land and binds successors in title. The beneficiary of the covenant, usually a government department or a conservation trust, may enforce its terms in the courts.

This systems exists in only a few countries. In Australia, both the Commonwealth Endangered Species Act and state legislation in New South Wales provide opportunities for private landholders to enter voluntary 'conservation agreements' or 'heritage agreements' with the government, which are then binding on current and future landowners. In the United States, some states have a form of covenant called 'dedication' that additionally preserves the land from expropriation by government agencies. In Samoa, where customary ownership rights are recognized by the state, local communities have covenants with private and government institutions to conserve the rain forests. These reserves suggest that solutions to biodiversity conservation may be achieved under local control (Cox and Elmqvist 1991).

13.6.3.2.3 Easements. Easements are contracts that impose specific obligations on owners. They run with the land and bind successors in title. Developed under rural law, they secure a benefit (e.g. a right of way) for one piece of land at the expense of contiguous land. A small number of countries now permit the creation of easements for conservation purposes and waive the contiguity requirement. A conservation agency or NGO can contract with a landowner to prohibit certain forms of land use, and future owners must comply with these prohibitions. A conservation body may, in some cases, sell its own land with a conservation easement attached.

In the United States, voluntary arrangements that obligate not only those entering into them but also successors in title are called *conservation easements*. Under the common law as it has developed in the United Kingdom and Australia, they are referred to as *restrictive covenants*. Restrictions may be placed by the law on those who are allowed to take advantage of easements (Farrier 1995). Historically in common law jurisdictions, only negative obligations, relating to land use or land-use restrictions, bound successors in title. Legislation now frequently allows positive obligations (management obligations). For example, in the United States, conservation easements are often empowered by legislation to impose positive management obligations as well as negative restrictions (Farrier 1995). Cheaper than acquiring the land itself, easements are a very flexible instrument, although they may not generally include positive obligations.

13.6.3.2.4 Management agreements. These are contracts between public authorities or conservation organizations and landowners who undertake to manage their land in a specified way in return for periodic payments or a lump sum. If management agreements run with the land and contain positive obligations, such as those concluded for SSSIs in Great Britain or Heritage Agreements in South Australia, then they are particularly useful for the long-term conservation of areas rich in biodiversity.

Alternatively, management agreements may take the form of personal contracts with the landowner that are concluded for a relatively short period of time. These instruments are increasingly used to promote extensive agriculture and the conservation of landscape features and semi-natural habitats. The European Union initiated this type of contract in 1985. Farmers may enter into agreements whereby they are paid to manage their land according to ecological criteria. The system, originally limited to designated Environmentally Sensitive Areas, is now applicable in the whole of the territory of the member states. Similar systems have been developed in several countries outside the European Union, such as Sweden.

Another type of management agreement is Countryside Stewardship, developed in the United Kingdom, which aims to combine conservation and public enjoyment of land with commercial land management through a national system of incentives. The scheme is not area-specific, nor is it restricted to farmers. Proposals for the management, restoration or re-creation of specified categories of habitats or landscape features are screened, and only the best from an environmental point of view are retained. Agreements run for ten years and a sliding scale of premiums is paid per hectare, depending on the complexity of the conservation obligations involved.

Simple contracts for the protection of habitats or for other actions to manage biodiversity sustainably, that obligate only those entering into them and do not impose obligations to successors in title, are of limited utility for long-term biodiversity conservation since they are vulnerable to changes in ownership.

13.6.3.3 Combining regulatory and voluntary measures

Just as an exclusive reliance on regulation can limit the effectiveness of protection and sustainable use measures, the entirely voluntary approach to conservation on private lands can have serious limitations as well. Not only would this be extremely expensive, but it gives individual landowners the power to veto the use of conservation measures on their land, for example, under a broader strategy to create a buffer zone or a wildlife corridor. This suggests that the most effective legal strategies to sustainably use and protect biodiversity will include a combination of 'carrots' and 'sticks' (Farrier 1995). Regulatory measures can be made more acceptable by reducing taxes or granting fiscal benefits with respect to land subject to restrictions for conservation purposes, and/or by compensating the landowner for loss of profit.

The SSSI system in the United Kingdom is partly regulatory (prior notification to be made before certain operations are conducted) and partly voluntary (management agreements are freely negotiated). Where parties fail to reach an agreement, the conservation authority has the back-up regulatory powers to make

conservation orders in respect of sites of particular value or to purchase the land compulsorily.

Under South Australia's Native Vegetation Act (1991), when a permit to clear native vegetation is refused, the government may offer to buy the land and re-sell it with a Heritage Agreement attached or to conclude such an agreement directly with the landowner. Agreements run with the land and restrict its use, since owners may be required to carry out preservation and enhancement works or to permit the government to do so. The Heritage Agreement may provide compensation for loss in land value resulting from the agreement, but compensation is not paid for loss in land value resulting from restrictions on clearance of native vegetation. An Agreement may also commit the conservation authority to provide technical assistance to the owner to undertake ongoing management and planning.

Where an owner, such as a conservation NGO, wishes to preserve a site and needs assistance from the government, regulatory measures should aim to prevent encroachment by third parties and by government agencies. In Belgium and France, once voluntary reserves have been approved by the government, they are protected as statutory reserves, except that owners remain free to abolish them.

The United Kingdom's National Trust, a major owner of land and buildings for conservation, may declare its land inalienable. Such land cannot be sold or donated, nor may it be compulsorily purchased unless Parliament decides to the contrary. Like its sister bodies in several Commonwealth countries, the Trust may make and enforce restrictive covenants with other landowners over their property. National Trusts usually also have the right to make bylaws binding upon third parties.

Few voluntary instruments have yet been created to preserve species or manage potentially damaging processes. Regulatory measures continue to dominate those sectors, so imaginative thinking is clearly necessary. The various South Australian experiences over the past several years to persuade landowners not to clear native vegetation provide an interesting case study in the failure of command and control legislation on the one hand and pure voluntarism on the other. The original South Australia Native Vegetation Management Act of 1985 combined command and control with compensation for the imposition of land-use restrictions. The successor 1991 Native Vegetation Act is attempting to move away from compensation for restrictions toward providing incentives in the form of management payments for active conservation steps.

13.6.3.4 Environmental impact assessment and other legal institutions and procedures for conserving biodiversity

Environmental impact assessments are strategically important legal tools for protecting biodiversity because they seek to avoid problems before projects are

implemented. They should be required for sectoral and land-use policies, programmes and plans – particularly highway planning, river basin development, forestry and physical planning. It is often too late at the project stage to prevent major damage if that project is already part of an approved plan or programme.

The Preamble to the Convention on Biological Diversity states that the contracting parties 'note that it is vital to anticipate, prevent and attack the causes of significant reduction or loss of biological diversity at source'. Environmental impact assessments (EIAs) are the most important legal procedure for achieving this objective, and several provisions within the convention – most notably Article 14 (Impact Assessment and Minimizing Adverse Impacts), Article 7(c) and Article 8(l) – specifically address the types of knowledge and assessment needed to reach an ecologically appropriate decision. Where it appears from the EIA that an important and threatened element of biodiversity is likely to be significantly affected by the proposed project, a decision to let the project go ahead should be allowed by law only in exceptional cases.

The law should, as in Italy, specify the elements of biodiversity to be considered when preparing the EIA and require its content to be verified by the conservation agency or an independent body. As yet, very few countries have adopted special rules for projects liable to affect ecologically sensitive areas by requiring EIAs to be prepared for certain categories of projects that would normally be exempt.

The law should clearly establish conditions of participation in the decision-making process, and should cover consultation of scientific bodies and conservation NGOs, the right to comment on EIAs, and access to information on the environment and threatening activities. Mechanisms should be established to resolve conflicts between conservation and development, through mediation, an intervener or ombudsman, or the courts.

In law or pursuant to judicial practice, conservation NGOs in a few countries have standing to sue for breach of the law, a particularly valuable procedure where government has violated its own regulations. Standing is necessary to ensure that:

- governments do not issue regulations or permits against the law;
- proper assessment and consultation procedures have been followed, and
- proceedings may be brought against offenders where public authorities refuse to intervene.

Few laws deal adequately with the problem of compensating damage to biodiversity. There are three mainly unresolved problems: the definition of the damage to be compensated; the evaluation of the damage (certain countries, such as Spain, have a scale for protected species);

and the identity of the person or body to be compensated (Italian and Spanish laws nominate the government, but in most countries, no one can sue or collect for damages unless a direct interest has been injured).

Box 13.6-1 illustrates a framework used in India to analyse the coverage of legal measures with respect to biodiversity resources and activities impacting biodiversity. Table 13.6-2 shows the results of the analysis.

13.6.4 International law

Until relatively recently, international law evolved unaware of and seemingly unaffected by global environmental interdependence. In governing the relations among states, traditional international law focused on recognizing and preserving each state's sovereignty. Its underlying assumption was the freedom of control over activities within a state's national jurisdiction. Sovereignty historically included freedom of action with regard to the natural resources found within a state's national jurisdiction. The earliest limitations on activities within national boundaries consisted of narrow formulations based on the general international-law obligation that no state should permit its territories to be used to harm its neighbours.

The last 20 years have witnessed a growing understanding and acceptance of the global nature of environmental degradation. Countries at the Stockholm Conference on the Environment in 1972 accepted the declaratory principle that nations have the sovereign right to exploit their own resources *and* the responsibility to ensure that activities within their borders do not cause damage to other nations or international waters (Bragdon 1992). The Convention on Biological Diversity was the first agreement to take this principle and include it in the legally binding text of a treaty. The scope of activities taking place within national jurisdictions but affecting the environment of the international community is larger than previously imagined, and the earliest limitations on national sovereignty have grown accordingly.

13.6.4.1 Regional and sectoral treaties

Nations will voluntarily restrict their sovereignty rights by consenting to be bound by international treaties when it is in their interest to do so. The evidence of global environmental interdependence has created incentives for collective action, and the number of multilateral environmental treaties now exceeds 150 (Bragdon 1992). In addition to the Convention on Biological Diversity, which takes a comprehensive approach, there are four global treaties (concluded prior to the CBD) that address specific aspects of biodiversity. These are:

- The Convention Concerning the Protection of the World Cultural and Natural Heritage (1972), or the World Heritage Convention;
- The Convention on International Trade in Endangered Species of Wild Fauna and Flora (1979), or CITES;
- The Convention on the Conservation of Migratory Species of Wild Animals (1973).

Other treaties have been concluded to promote the sustainable exploitation of dwindling shared resources, such as the Whaling Convention of 1946. Codified rules on fisheries jurisdiction and harvesting of living marine resources are now embodied in the global Law of the Sea Convention (1982; UNCLOS), in force from 1994. Although the Convention does not expressly deal with biodiversity, it regulates the introduction of species and contains a general obligation to preserve rare and fragile ecosystems and habitats of endangered species.

The first wildlife conservation treaty, the Convention for the Protection of Birds Useful to Agriculture, was concluded in 1902. It was followed by the signing of several regional instruments: London Convention (1933, for Africa); Washington Convention (1940, for the Western Hemisphere); Algiers Convention (1968, replacing the London Convention); Agreed Measures for the Conservation of Antarctic Fauna and Flora (1964).

At the regional level, protocols have been concluded under certain Regional Seas conventions to implement the provisions of UNCLOS on the protection of ecosystems in the Mediterranean (Geneva 1982), East Africa (Nairobi 1985), the Southeast Pacific (Paipa, Colombia 1989), and the Caribbean (Kingston, Jamaica 1990).

In Europe, the Berne Convention (1979) requires the protection of listed species and endangered habitats. European Union directives binding upon member states are the Birds Directive (1979), which requires the establishment of Special Protection Areas for birds, and the Directive on the Conservation of Natural Habitats and of Wild Fauna and Flora (1992), which lists species whose habitats must be protected by member states. Particularly innovative is the obligation to preserve endangered habitat types as listed in an annex. The directive provides for the establishment of a network of Special Areas of Conservation, NATURA 2000.

Other regional instruments include the Apia Convention for the South Pacific (1976) and the ASEAN Agreement (1985), which is the most comprehensive regional treaty on environmental protection.

The Madrid Protocol of 1991 to the Antarctica Treaty (1959) designates the Antarctic as a 'natural reserve devoted to peace and science'. Activities in the Treaty Areas must be planned and conducted so as to 'avoid detrimental changes in the distribution, abundance, or

Box 13.6-1: Legal coverage of biodiversity conservation and use in India.

Each country needs to assess the legal coverage of biodiversity conservation and use within its boundaries. Such an assessment has been broadly carried out for India (Kothari and Singh 1992). This assessment first provides a conceptual framework within which to examine each law, and deals not only with conventional conservation laws but also other laws relating to development, use and distribution of resources.

For the sake of the analysis, Kothari and Singh (1992) categorized biodiversity components under five headings: wild fauna, wild flora, domesticated fauna (livestock), domesticated flora (crops and other cultivated plants), and genetic materials (seeds, eggs, germplasm, semen). They also distinguished 11 distinct aspects of biodiversity:

1. *Identification*: The process of locating, and thereafter establishing the identity, distribution, occurrence, status, and value of biodiversity components. Relevant to both wild and domesticated fauna and flora.
2. *Protection in situ*: Efforts to protect and conserve biodiversity, including the habitats within which biodiversity components survive and evolve. Applies especially to wild fauna and flora, but also to domesticated fauna and flora at the sites of their use, in so far as these may need to be protected from disease/infestation, displacement by new varieties, and destruction from human activities.
3. *Protection ex situ*: Attempts at preserving living species or genetic material in gene banks, zoological parks, botanical gardens and sites other than their natural habitats. Relevant to all biodiversity components.
4. *Access/extraction*: Controls on the kind and amount of access to fauna and flora in the wild, to *ex situ* collections, and to genetic material; also the modes of extraction of these components, relevant especially to *in situ* stock. Overlaps with intellectual property rights (see 11 below).
5. *Use*: Attempts at utilizing biodiversity for subsistence, commercial, scientific or other purposes. Relevant to all biological components.
6. *Breeding/Cultivation/Multiplication*: Artificial or induced measures for regenerating flora-fauna populations in captive or closed conditions. Relevant to both wild and domestic fauna and flora.
7. *Trade*: Activities relating to the barter, sale, import, export and other forms of exchange of biodiversity components.
8. *Introduction/Augmentation/Re-introduction*: Measures to deliberately stock an ecosystem or area with species that did not previously exist there (introduction) or where they have declined or need to be increased in number (augmentation) or where they have died out (reintroduction). Relevant to both wild and domesticated fauna and flora, as also to genetic material (e.g. seeds) used for the purpose.
9. *Release*: Disposal of biodiversity components, without the specific purpose of introducing, augmenting, or reintroducing them, into the environment. Relevant to all biodiversity components.
10. *Movement*: Measures to transport, by human means, biodiversity components from one location to another; especially relevant in cases of transportation across ecosystems or bioregions, involving the possibility of accidental release of components. Does not include natural or voluntary movement of animals, or movement of seeds or other floral parts by natural means. Relevant to all biodiversity components.
11. *Intellectual property rights*: Measures pertaining to the rights of the state, organizations, or individuals over biological and biotechnological knowledge, including patents, royalties, intellectual property rights, farmers' rights and breeders' rights.

Over 40 national Acts were then assessed with respect to their coverage (or lack of it) of each of the 11 aspects listed above for each of the five biodiversity categories (i.e. wild flora, wild fauna, domesticated flora, etc.). The results of this analysis are presented in Table 13.6-2.

productivity of species or populations of flora and fauna or further jeopardy to endangered species or populations'.

Lastly, a few treaties outside the Migratory Species Convention deal with migratory species such as polar bears, vicuna and migratory birds (e.g. several bilateral treaties, such as a 1916 bilateral agreement on migratory birds between the United States and Canada).

The above summary reveals that large parts of the world are covered by regional treaties, the content and rigour of which vary greatly, and that global treaties deal only with limited, if important, aspects of biodiversity conservation.

13.6.4.2 The Convention on Biological Diversity

The IUCN promoted the idea of a global convention on

Table 13.6-2: Legal coverage of various aspects of biodiversity in India.

biodiversity as early as 1981. The idea was supported by the World Commission on Environment and Development in its report, *Our Common Future* (WCED 1987), and in 1987, the UNEP Governing Council established an *ad hoc* working group to investigate ‘the desirability and possible form of an umbrella convention to rationalize current activities in this field’, and to address other areas that might fall under the convention. By early 1990 the group had reached a consensus that a global treaty on biodiversity was needed. The UNEP secretariat prepared a first draft of the convention, and formal negotiations began in November 1990. The convention was adopted in Nairobi in May 1992 and opened for signature at the United Nations Conference on Environment and Development (the ‘Rio Summit’). It entered into force on 29 December 1993 and as of 21 June 1995 had 118 Contracting Parties.

The convention affirms that the conservation of biodiversity is a common concern of humankind and sets forth objectives for conserving, sustainably using, and equitably sharing the benefits from such use. The negotiations made clear that the ability to reach and implement agreement on this subject depends on the ability to maintain this careful balance among objectives. The convention recognizes the sovereign rights that states have over their biological resources, but also the responsibilities they have for protecting their biodiversity and using it sustainably. Emphasis is placed on the importance of preventive measures and the precautionary principle.

Biodiversity is defined in the convention as ‘diversity within species, between species and of ecosystems’. Parties must promote the conservation of ecosystems, natural habitats, and the maintenance of viable populations of

species in their natural surroundings. *Ex situ* conservation is complementary to this objective.

The convention requires the creation of a system of protected areas, or areas where special measures need to be taken to conserve biodiversity, together with the identification, regulation and management of processes and activities that have, or are likely to have, significant adverse impacts on biodiversity. Parties must also enact legislation for the protection of threatened species and populations.

Parties must adopt national strategies, plans or programmes for the conservation and sustainable use of biodiversity. They are also required to prepare environmental assessments of proposed projects likely to have significant adverse impacts on biodiversity, and to ensure that the environmental consequences of programmes and policies likely to have such impacts are taken into account.

The convention empowers host countries to enact laws requiring companies to pay access fees and negotiate royalty payments with the suppliers of genetic resources. For the first time in international law, conservation obligations are balanced in the convention by certain rights, as a matter of equity and as an incentive to conserve biodiversity:

- Access to genetic resources by foreign collectors is no longer unrestricted, but is now subject to the prior informed consent of the party providing the resource. Host countries are therefore empowered to enact laws requiring companies to pay access fees and negotiate royalty payments with the suppliers of genetic resources, and conditions of access must be mutually agreed. The convention does not, however, outline

the procedures that governments must follow, and some may choose to have certain types of resources or resources for certain purposes (e.g. non-commercial scientific research) freely available.

- The results of research and development, and the benefits arising from the commercial and other utilization of genetic resources, must be shared in a fair and equitable way with the party providing the resource, again on mutually agreed terms.
- All Parties are required to provide and/or facilitate access to and transfer of technologies that are relevant to the conservation and sustainable use of biological diversity and do not cause significant damage to the environment. The transfer of such technologies to developing countries is to be provided on fair and preferential terms, where mutually agreed.
- Although these provisions do not explicitly affect intellectual property rights such as patents (although Article 16(5) states that IPRs should be supportive of and not run counter to the objectives of the convention), parties must facilitate through proper incentives the transfer of technologies even where protected by such rights.

These provisions on access do not expressly guarantee benefits to local people whose traditional knowledge often provides the initial basis for identifying seeds and plants that might have medicinal and other benefits. However, it should be noted that the conservation provisions of the convention require countries, subject to national legislation, to respect and maintain the knowledge, innovations and practices of indigenous and local peoples, and to encourage the equitable sharing of the benefits arising from the utilization of such knowledge, innovations and practices. Given the close connections between genetic resources and local and indigenous knowledge and innovations, countries may consider implementing this requirement in conjunction with any access regime it adopts or creates in order to implement the convention.

The convention's success will be determined in part by the willingness of developed countries to provide financial resources and technological transfer to poorer countries that are rich in biodiversity. Indeed, the convention explicitly links effective implementation by developing countries to the fulfilment of these obligations by developed countries (Article 20(4)).

The convention establishes a mechanism for the provision of financial resources to developing-country parties on a grant or concessional basis. At its first meeting, the Conference of the Parties to the Convention selected the Global Environment Facility to operate the financial

mechanism on an interim basis until a final decision by the Conference of Parties at its second meeting in November 1995.

Developed countries are to provide new and additional financial resources to enable developing countries to meet the agreed full incremental costs to them (i.e. costs to a developing-country party that exceed domestic benefits from actions taken to implement terms of the convention) arising out of their obligations under the Convention. It should be noted that benefits to developing countries should also flow from other financial institutions and mechanisms, such as genetic access agreements.

13.6.4.3 Implementation and compliance

Just as incentives are needed to bring nations to the negotiating table in the first place, so are incentives also necessary to ensure countries remain parties and implement their treaty obligations. In addition, implementation requires an adequate number of institutions to support and develop the treaty. These include a Conference of Parties (COP), a Secretariat, and perhaps relevant subsidiary bodies. The COP is a treaty's most important institution and has the primary responsibility for reviewing and directing its implementation. In order to fulfil this responsibility, the COP must have the power to review implementation, make recommendations to the parties, and adopt the budget and scale of contributions. Conventions that have not established institutions with adequate authority have not been active (examples include the Algiers and Western Hemisphere conventions). In addition, the RAMSAR Convention had to be amended almost 20 years after its conclusion to establish these basic minimums.

Many treaties require parties to present the COP with progress reports on implementation of the convention. This provides a mechanism by which implementation can be monitored. The information is used as the COP considers what action may be required for the achievement of the purposes of the convention in light of the experience contained in the report.

Specific procedures have been developed under certain conventions to improve compliance. The RAMSAR Convention has instituted a monitoring procedure for listed Wetlands of International Importance. Sites with particular problems of compliance are listed in the 'Montreux Record'.

The World Heritage Convention has a *List of World Heritage in Danger*, and the World Heritage Committee can de-list a site that has lost the intrinsic qualities that determined its inclusion on the list where the necessary conservation measures have not been taken. The CITES Standing Committee makes recommendations to parties to refuse CITES specimens from parties in breach.

The Berne Convention has a system for opening files in cases of non-compliance. Its standing committee discusses

cases, in the presence of NGOs that may contribute to the discussion, and makes recommendations to parties. The procedure is often initiated after an NGO has submitted information to the secretariat.

Adequate finance is essential to pay for meetings and to provide secretariats with properly qualified staff: however there is usually stiff resistance to increasing the low level of essential expenditure in the budget approved by the parties.

A convention's effectiveness also depends on whether financial assistance is available to help parties to comply with its terms. This objective is integral to the Convention on Biological Diversity. The only other convention to address this matter directly is the World Heritage Convention, whose World Heritage Fund is intended to assist parties in conserving World Heritage Sites. A Wetland Conservation Fund has now been established under the RAMSAR Convention.

13.6.4.4 Interaction between national and international legislation

National and international law are complementary and interactive (this is not generally true, however, between national laws and customary laws). Treaties are often concluded at the initiative of countries with more advanced national conservation laws. To meet these international obligations, less advanced countries then have to raise their own standards of legislation. As an example, the 'potentially damaging process' concept initiated by Australia is now part of the Biodiversity Convention, whence it will gradually be incorporated into the legislation of other countries.

The existence of international obligations gives greater legitimacy to national laws, facilitates their implementation and enforcement, and may require the promulgation of new laws to implement obligations assumed by becoming a party to a treaty. International co-operation resulting from treaties facilitates access to scientific, technical and legal information, which is essential for effective conservation.

13.6.5 Conclusion

This brief review has highlighted the variety of legal instruments available for the conservation of biodiversity. Traditional tools for the protection of species and areas, based on regulatory measures, are increasingly complemented by voluntary systems based on contracts and incentives. There is a pressing need to make comparative studies of existing instruments and their successes and failures, and to make this knowledge available to conservationists the world over to stimulate innovative and effective legislation.

Law should form an integral part of conservation science, yet its role and potential are often still not fully appreciated by conservationists. Legislation cannot substitute for effective biodiversity management

programmes. Biodiversity management efforts, however, will work most effectively within a legal framework that provides regulatory and incentive tools that provide the authority needed to implement conservation and sustainable use activities.

13.7 Building capacity for biodiversity management

13.7.1 Introduction

The development and implementation of successful biodiversity policies depends on the capacity of the people to carry out a number of related intellectual and practical tasks. To achieve an integrated and comprehensive biodiversity management programme, a country will need to provide opportunities for its citizens to develop the relevant scientific, technical and administrative knowledge. A set of institutions, physical facilities and financial resources will also be required to support their work. Experience shows that the potential for success can be realized when policies, activities, investments, and public and political actions promote these ends.

Four types of capacity can be considered:

- human capacity
- institutional capacity
- facility (infrastructure), and
- financial capacity.

Little, if any, comprehensive assessment has been conducted – at either national or international levels – to detail the existing and required capacities in these four areas. Thus, in each section below, only limited examples can be offered to document the concepts and principles involved.

13.7.2 Human capacity

People are ultimately the most important resource for designing and implementing a biodiversity management programme. This is recognized in the United Nations Development Programme's (UNDP) 'Capacity 21' programme. Designed in the wake of the UN Conference on Environment and Development, the programme is an effort to build the human capacity necessary to implement Agenda 21, and the international agreements signed in Rio de Janeiro (UN 1993).

Biodiversity management requires the use of many different human skills and capacities. Box 13.7-1 shows the

types of fields and training needed by typical biodiversity management programmes. These fields range from basic sciences through practical fieldwork, policy analysis and business management, to community organization and rural extension. Academic training and other forms of human resource development for biodiversity management may take place at universities, trade schools and specialized training programmes and at the community level. Distinct from traditional educational processes, biodiversity management calls for considerable integration and co-operation among professions and academic disciplines in order to bring the best science, traditional knowledge and field know-how into practice. It also requires integration among public and private interests including business, communities, public natural resource managers, and individual farmers, foresters and fisherfolk.

The design and management of methods to develop human capacity are culturally dependent. Existing skills and knowledge from across a wide spectrum, from local villages to government departments, need to be inventoried, evaluated and encouraged. Some of the most prominent methods of fostering human capacity include those listed in Box 13.7-2.

These methods are already being employed to expand biodiversity capacity. Important examples include joint activities among specific countries and bilateral and multilateral assistance agencies to formulate country studies, national strategies and action plans (Miller and Lanou 1995). Numerous opportunities to develop human capacity already exist in the form of technical training courses and workshops on such issues as inventory and data management, taxonomy and genetic resources conservation, biodiversity project planning, and strategic planning and legislation for biodiversity management.

Experience indicates that one way to develop people's skills is to involve them in the preparation of national strategies and action plans. Enabling 'biodiversity planners' also to be 'biodiversity implementors', encourages policy makers, scientists, resource managers and local leaders to gain an understanding of the problems and opportunities in the field, and take responsibility for the implementation and evaluation of their decisions.

Networking about experiences and information has been facilitated by new on-line computer technology and electronic mail systems. The FAO/UNEP Latin American Regional Network on Wildland Management, for example, was launched in 1983 to establish an efficient method of exchanging professional experience and fostering regional co-operation on protected areas and wildlife management in the Latin American and Caribbean region (Thelen 1992). Other networks exist among botanical gardens (Botanic Gardens Conservation International at Richmond in the UK), national parks and protected areas managers (IUCN

Commission on National Parks and Protected Areas, Gland, Switzerland), indigenous knowledge facilitators (International Development and Research Council, Ottawa, Canada), species specialist groups (IUCN Species Survival Commission, Gland, Switzerland), mycologists (Centre for Agriculture and Bioscience International, UK); agricultural germplasm (International Plant Genetic Resources Institute, Rome), forestry (International Union of Forestry Research Organizations, Vienna, Austria), community-level agro-ecology (Centro de Educación y Tecnología, Chile) and the IUCN Centre for Environmental Law, among others (CET 1991; Hawkes 1991; Hoyt 1992).

How much capacity exists for any of the many skills and occupations discussed above is difficult to assess, although it is clear that what capacity does exist is found mostly in developed countries. For example, Figure 13.7-1 shows that very few plant ecologists are found in regions where the greatest plant diversity is located. It is likely that similar relationships would be found for virtually any other discipline or skill.

Even less is known about what additional capacity is needed to manage biodiversity adequately. Some assessments for particular disciplines have been made. For example, China has estimated that at least 30 more botanists and 50 technical specialists are needed to complete the floristic inventory of its tropical region alone. The cost of this added level of personnel and their material support would be US\$2 million annually (Wang Huen-pu *et al.* 1989). To some extent, national biodiversity country studies, strategies and action plans are assessing what kinds of human resources are needed to carry out a comprehensive integrated biodiversity management programme. For example, the Biodiversity Action Plan for the United Kingdom emphasizes the need to develop the capacity to carry out an expanded environmental education programme (Government of the United Kingdom 1994). The Thailand Biodiversity Country Study estimates that \$113 million is needed for investment in education and training in fields relevant to biodiversity management. Most of this funding (75%) will require external financial assistance (Ministry of Science, Technology and Energy 1992). In Kenya, the national biodiversity plan estimates that 42 additional scientists and 84 technicians are needed over the next four years to achieve its genetic resource conservation goals (Government of Kenya 1992). While some of the training can be done at national institutions, additional postgraduate training will be needed abroad.

13.7.3 Institutional capacity

As noted in previous sections, institutional capacity varies from area to area because information, government policies, laws and administrative procedures and the cultural norms of each society are so different. Such

Box 13.7-1: Basic fields of human capacity for biodiversity management.

ecosystem science	natural resource planning/management
landscape ecology	community extension
conservation biology	environmental education
population biology/genetics	natural resource economics
plant and animal technology	marketing
biotechnology	business management
pharmacology	public administration
agro-ecology	project design and management
marine biology	policy analysis
systematics/taxonomy	anthropology and other social sciences
inventory	tourism management
monitoring	plant animal selection, breeding
captive breeding	garden and orchard management
urban/regional planning	natural products (chemical) research
restoration ecology	community organization
medical research and healthcare	environmental education
environmental and international law	bioregional/ecosystem management

aspects can either foster or impede the planning process.

While many institutional arrangements are formalized, with an organization to carry them out, others remain informal, and free of structure and bureaucracy. In the former instance, governments establish agencies to administer everything from water resources and national parks to agricultural research, seed banks, germplasm facilities and training centres. In some cases, communities, religious and interest groups, and industry establish formal organizations to create opportunities for training and citizen involvement in biodiversity management activities.

More informally, some traditional groups maintain systems of land distribution and use, crop management, water rights and other features of biodiversity management that remain outside the established formal institutions (see also 13.3, 13.5 and 13.6). For example, in Northern India, the management of livestock around water-holding ponds and the distribution of water for irrigation purposes provide a strong institutional structure for long-term continuous use and protection of upstream catchment lands, ponds, and agricultural soils (Poffenberger 1990).

Four major institutional issues confront many efforts to manage biodiversity. The first involves the loss of control by traditional or local institutions over natural resources, for example, where central government agencies have established control over forests previously managed by the community. In this case, informal institutional arrangements of traditional forest dwellers and/or users are superseded by central government regimes. These regimes often do not offer alternative access to resources or

compensation for these people, nor do they establish a new mechanism with adequate capacity to sustainably use and protect the resource (see, for example, Poffenberger 1990; Johnson and Cabarle 1993). Commonly, timber and other commercial commodities are exploited by non-local groups who gain a public subsidy for road building and low resource-extraction fees. This leaves the traditional communities without their own resource base and with little or no benefit from the new and different forms of resource use (see, for example, Sizer and Rice 1995).

Conflicts over the balance between central and local control over resources and management authority is found in many countries, developing and developed alike. One view suggests that the management responsibility and authority over natural resources including biodiversity is most effective when it is in the hands of local institutions. This perspective argues that under local control, the biota will be more efficiently protected and used, and the benefits more appropriately shared; this is because only at that scale can experience with local ecosystems and cultural attributes be properly mobilized. Furthermore, this argument proposes that direct local involvement can provide the incentive for commitment by local people to longer-term cycles of harvesting and use, as well as to stewardship, maintaining ecosystem health, and the production of a steady stream of benefits (Lynch 1992).

This view is countered by arguments that local control will foster over-harvesting for short-term local gain. Local power will ignore the greater national and societal interest. A compromise approach suggests that governments can choose to exert normative control over natural resources

Box 13.7-2: Measures for developing human capacity to manage biodiversity.

- Short courses on specific scientific, technical, managerial, or administrative topics.
- University and post graduate-level degree work in key fields, both in the country and abroad.
- Workshops and seminars on particular issues.
- Professional and academic exchange between countries or institutions to share experience and methods (North–South, South–North, and South–South).
- Programmes to train extension workers.
- Programmes to prepare, translate, and distribute training materials.
- Planning exercises that both prepare plans and provide the opportunity for intimate involvement of interdisciplinary and inter-sectoral collaboration.
- Networks of expertise and institutions to foster communication, exchange of experts, and sharing of information and experience.
- Consultant experts (local, traditional, and international).
- Rural worker group activities to share experience on methods and techniques.
- Events that permit exchange of information and methods between government and private sector scientists and technologists, and rural experts.
- Rural extension activities to promote exchange from rural to formal, and the reverse.
- Preparation of country studies, national strategies, and action plans involving government agencies, rural communities, business and industry, indigenous groups, and other stakeholders.

management as measured by agreed indicators and norms. Under this approach, day-to-day management would be left to local public and private institutions. One example is the Great Barrier Reef Marine Park Authority, where protection activities are managed by the National Park Service of the State of Queensland, through an agreement with the Commonwealth Authority (Great Barrier Reef Marine Park Authority 1993).

A second important issue is that of creating equal opportunities for all interested parties to be aware of the issues and options, and to gain access to knowledge and

information. If business, communities, and agencies are to define and achieve their goals equitably, all parties must have full access to information about the problems and opportunities, status and trends. *Agenda 21* documents the commitment of world governments to improving access to information from official to unofficial circles (UN 1993), a move that arguably is essential if farmers, forest workers, fisherfolk, industry, local government and community organizations are to become ‘biodiversity implementors’.

Third is the issue of encouraging and developing local participation in nationally and internationally agreed measures to support biodiversity management projects. Anecdotal evidence suggests that local scientists, resource managers, community leaders and others managing biodiversity are poorly compensated for their work. They have little involvement in the national and international debate, and are granted little political and social status. National experts are often not consulted by their own governments with regard to the development of policy or international agreements. In too many places, foreign experts are still being hired in spite of local expertise being available. This wastes opportunities to engage and promote the learning and commitment of national and local experts, with the result that talented local experts often seek opportunities elsewhere.

The fourth issue is that of institutional flexibility. In other words, can institutional arrangements and organizations be sufficiently flexible and adaptive to respond to evolving knowledge, environmental conditions, policies, and opportunities? Recent work on adaptive management approaches (e.g. Holling 1993) suggests that management systems will be more effective over the long term if they deal explicitly with change (climate, evolving biotic structures and processes, human settlement patterns, population growth, technology, world markets, etc.). To respond to change, shifts in the mandates and structures of some agencies may be needed. For example, new responsibilities and authorities may have to be assigned to study, inventory, protect and develop biodiversity. New and changing private and community firms and organizations may develop with growing opportunities to develop and distribute bio-products and to foster the sharing of costs and benefits within local communities. The work of the South Pacific Regional Environment Programme demonstrates a specific effort among small island states to establish joint cooperative activities, beginning with a co-operative protected areas project (Reti 1995).

Institutional arrangements and organizations need to grow, change, and adapt for several reasons:

1. Biodiversity management is inter-sectoral. New and evolving mandates and responsibilities can be anticipated among such diverse sectors as forestry,

Figure 13.7-1: Distribution of professional plant ecologists in relation to the distribution of plant species richness.
(Source: WRI/IUCN/UNEP 1992.)

social affairs, range management, fishing, agriculture, germplasm, museum collections, university departments of phytochemistry, business administration and economics, national park services, wildlife departments, and legal and patent offices.

2. Implementation requires resource-using industries, local communities and indigenous groups to collaborate in their own self-interest, perhaps leading to the reconsideration of old and traditional arrangements and attitudes.
3. The geographic scale of biodiversity work reaches to new configurations of land and water territory, embracing whole ecosystems or bioregions, thereby cutting across established agency jurisdictions.

Thus, conservation practice can no longer be seen as a responsibility covered only by protected areas, endangered species legislation, seed collections and trade regulations. In addition to these important components, biodiversity management requires new alliances and perspectives.

The critical issue is whether established public agencies, educational programmes, and the private sector can change their approaches to biodiversity protection and use. As Einstein once said, 'We cannot solve the problems that we have created with the same thinking that created them.'

Can existing institutions effectively change to meet the articles of the Convention on Biological Diversity? Can old mandates, structures and styles and cultures of work address what are substantively new requirements and opportunities?

For example, current rates of biodiversity loss are caused at least in part by inappropriate and even perverse policies and incentives (see Section 12). Public agencies have jurisdictions that overlap; landscapes and ecosystems are fragmented not only ecologically but also administratively. For example, salmon and other commercial fish species may pass through areas under the management of several public agencies and community-based management systems as they swim from the open sea to upper stream spawning areas. Marine turtles swim through international waters, through the nearshore coastal areas of different countries, and up on to beaches near local communities where they lay their eggs. Can public and community organizations establish co-operative regimes that cut across arbitrary (for biodiversity management purposes at least) administrative lines and focus on the real biodiversity issue? How can we protect and control the use of salmon and marine turtles throughout their range?

Creative approaches to institutional change are, however, being tried to manage biodiversity more effectively. Colombia's new constitution explicitly addresses the needs of biodiversity conservation and sustainable use, as well as

the security of indigenous peoples (Jacanamejoy 1994). Canada has developed a round-table process at the provincial level to draw local residents and into the preparation of its national biodiversity strategy (NRTEE 1993). Costa Rica's Ministry of Natural Resources has expanded the scale of its protected areas planning, building upon key traditional national parks to embrace whole bioregions, such as the La Amistad Biosphere Reserve, in co-operation with local governments and residents and the Government of Panama (Gobierno de Costa Rica 1990). Bilateral, multilateral and private funding sources have demonstrated a willingness to support work by governments and NGOs to establish and protect sites, collect plant and animal materials, develop new software programmes for computerized databases, and work with local communities as they seek sustainable resource-use patterns (Metcalf 1993). The US-based INTERGRAPH corporation is assisting the Costa Rican National Biodiversity Institute develop advanced software programmes for the management of complex biodiversity information. The UK Overseas Development Administration (ODA) is assisting Bangladesh to build a national herbarium with associated training programmes.

13.7.4 Infrastructure capacity

An array of building structures, transport services, communications devices and equipment is also needed to support a wide range of activities, such as those listed in Box 13.7-3. But investment in facilities, however necessary, poses a dilemma. While sources of funds for structures and equipment are relatively easy to find, it is often difficult to find the resources to maintain infrastructure. In addition, infrastructure investments are typically made in or near urban centres, especially near capital cities – far away from many of the areas most important for biodiversity management.

Furthermore, where investments in physical structures are made in place of investments in human resources, there may be an implicit bias in favour of government agency, university, and industry-based work instead of efforts supporting rural farmers, forest workers, fisherfolk, wildlife-based communities and local government. The aim should be to facilitate the work of all those elements called for in the national biodiversity plan. Typically, a national budget may well include funds for a mixture of investments and expenditures drawn from a number of the items contained in Box 13.7-3. The challenge to governments and other involved institutions is to find a balance between expenditures on physical plant and equipment, and expenditure on the other material needs of biodiversity management activities.

13.7.5 Funding capacity

Human capacity, institutions and facilities all require financial support to cover capital assets (e.g. buildings,

equipment, transport, land, etc.) and recurrent costs (e.g. salaries, personal benefits, travel, supplies, rent, energy and fuel, waste disposal, maintenance, insurance and overheads). Despite evidence of modest growth in conservation funding support in recent years, it is clear that biodiversity needs continue to vastly exceed the financial resources available. All countries and institutions involved in biodiversity management face questions about how existing financial resources should be allocated, and where and how to raise the additional funds needed to meet management objectives. And while funding overall falls short of requirements to adequately manage biodiversity, some countries have been overwhelmed by international assistance for biodiversity conservation. Donors, therefore, should deliver foreign assistance in ways that build, but do not swamp, a recipient country's 'absorptive capacity'.

Finance for biodiversity management is provided by three main sources: national and state/provincial government appropriations; private foundations and individual contributors to non-governmental organizations; and international bilateral and multilateral donors in the case of many countries in the tropics and eastern Europe. Decisions about funding biodiversity are complex for several reasons. First, most issues and options for action and investment involve multiple costs and benefits. Some potential investments will produce direct and tangible benefits in terms of food and nutrition, fibre and materials, water and soils, and tourism and recreation. Other investments will produce more indirect and often speculative benefits, such as potential medicines, new foods and improved crops. Some potential investments are in activities that produce benefits for overall regional and global geochemical, climatic and hydrological processes, but they may not be high priorities at national or local levels. In this latter case, it is presumed that global financial mechanisms, such as the Global Environment Fund, should cover the cost on behalf of the global community (see Section 12 for discussion of valuation and incremental costs).

A variety of new and innovative funding mechanisms, including debt-swaps, public/private co-financing, and trust funds dedicated to biodiversity management, have been developed in recent years (see Section 12). Among the most promising are 'national environment funds' established within individual countries under local boards of directors (e.g. Bolivia, Bhutan and Indonesia). Such funds are established under national legislation, and have a board of directors made up of local, national and international experts, and formal administrative procedures for the receipt, management and disbursement of funds. Funds can come from a variety of sources – international donors, private foundations, individual contributors and government appropriations. Typically, national environment funds do not themselves engage directly in project

management. Rather, they restrict their role to facilitating local management by other groups, including communities and NGOs (Dillenbeck 1994).

Such funds have several advantages over conventional annual government appropriations and donor-driven project financing. First, funds are allocated through a deliberative process involving knowledgeable and experienced board members who are, at least hypothetically, representative of those involved in the country's management of biodiversity. Second, since the resources in a national environment fund can be disbursed slowly or rapidly according to needs, they may avoid situations where a country's absorptive capacity is overwhelmed, or promising projects are ended arbitrarily, because of uncoordinated donor programmes. Third, in countries where biodiversity management relies on external support, national environment funds allow recipient countries to have more influence on where funds go to meet national biodiversity management goals. Fourth, if properly established and managed, national environment funds

provide a mechanism that is accountable to the public and to donors for the wise use of biodiversity management funds.

It is extremely difficult to estimate how much is now being spent, globally, on the management of biodiversity. Funding levels for some biodiversity management activities, protected areas in particular, are better documented than others. Based on data from IUCN (1994a) and WCMC (1992), protected areas budgets world-wide now total approximately US\$4.1 billion. This amounts to roughly \$450 per square kilometre per year for protected areas included in the IUCN World List of protected areas (IUCN 1994b). By comparison, the world spends \$1 trillion on defence and \$245 billion on agricultural subsidies (WRI/IUCN/UNEP 1992). To manage biodiversity effectively on a global basis, the Global Biodiversity Strategy (WRI/IUCN/UNEP 1992) estimated that approximately \$17 billion is needed annually. This estimate, however, is extremely rough; no systematic assessment with clearly defined objectives and assumptions has been made.

Box 13.7-3: Typical biodiversity activities requiring installations and implements.

Protected areas: housing for personnel, research laboratories, interpretative and educational structures, storage for collections, computers for data, monitoring devices.

Botanical gardens, zoological gardens, germplasm banks: housing for personnel, structures for storage and display of resources, educational and research facilities, grounds for out-planting, grounds for 'bulking up' plant and animal materials prior to reintroduction and restoration work, networks of village-based seed storage facilities.

Laboratories and research centres: taxonomy and storage, equipment for chemical extraction, analysis and research, experimental areas, educational and visitor equipment and access, and dormitories where needed to facilitate full participation of workers often from scattered rural sites.

Captive breeding centres: buildings, laboratories, corrals, grounds.

Local plant and animal propagation and breeding sites: rural grounds, greenhouses and planting beds, corrals and pens.

Rural extension and community centres: meeting sites with necessary buildings and communications equipment.

Transportation: various types of vehicles for transporting personnel, hauling plant and animal materials, surveying and inventorying of often vast terrestrial and marine areas.

Training centres: in conjunction with universities, rural community centres, public agencies, private enterprise and local government, a series of suitable buildings, meeting room furnishings, educational and communications equipment.

Customs stations and biosafety facilities: possibly in conjunction with established national customs installations, equipment needed to examine, store, test, quarantine and distribute or dispose of imported exotic species and genetically modified organisms.

Figure 13.7-2: Financial support from US sources to biodiversity conservation activities in developing countries.
(Source: Abramovitz 1994.)

Clearly, however, much more funding is needed, especially in developing countries where the greatest biotic wealth is found, alongside the least capacity to manage it. Abramovitz (1994) estimates that funding for biodiversity conservation in developing countries from all sources in the United States, including government, private foundations, and NGOs, totalled US\$105 million in 1991 (see Figure 13.7-2). The World Conservation Monitoring Centre is conducting additional surveys to better assess international funding levels around the world.

The GEF intends to allocate approximately US\$250 million annually for the three years 1995-1997 to biodiversity management projects. Recent evaluations of the GEF's pilot project phase concluded that the programme has had mixed success (Bowles and Prickett 1994; UNDP/UNEP/World Bank 1994). The most important problems have been a lack of participation by local communities and government leaders, and a mismatch between short-term, large-scale project funding and the long-term needs, and small or modest project capacity, of recipient countries.

In developed and developing countries alike, new and additional financial resources for biodiversity management are limited. Therefore, before seeking additional funding biodiversity planners should first ask if changes can be made within existing budgets to meet biodiversity goals more effectively. For example, can existing protected sites meet biodiversity conservation objectives with small budget changes? If new sites are needed, what is the least-

cost approach to meeting habitat and biodiversity representation goals? Can botanic garden and zoo programmes be shifted to focus more on local species? Should existing species collections focus first on national biota of scientific, educational and economic interest?

In most countries, biodiversity management has largely been the responsibility of public sector institutions, while private sector institutions in a wide range of activities from agriculture to ecotourism have benefited from these investments. What role can the private sector play in supporting biodiversity management? If the role of the public sector is to focus on establishing and managing protected areas, education, basic and conservation biology research, monitoring and strategic planning, should the private sector, including NGOs and business, play more of a role in other areas? For example, should the private sector take more of a role in supporting the inventory, characterization and assessment of species because of their link to potential new products and services? What incentives are needed to encourage the private sector to play a larger role in biodiversity management? Other roles and balances can be considered. Finding an appropriate balance between public and private sector involvement in biodiversity management is a process that has just begun.

Where existing budgets fail to cover financial requirements to meet objectives, to what extent should a country borrow or seek international financial co-operation for biodiversity management? The biotic wealth of a nation is considered by some to be perhaps the most sensitive and

sovereign of a nation's assets, aside from its people. What are the ethical and legal implications of using biotic wealth as collateral for loans or other market or trade arrangements? The Convention on Biological Diversity includes a commitment by the wealthier parties to share in the investment costs needed to help less wealthy nations protect their biodiversity and to shift to sustainable use practices.

13.7.6 Conclusion

Section 13 has illustrated an array of options for the protection and sustainable use of biodiversity and biological resources. There are tools and mechanisms available for the protection of species, genetic variation, habitats and ecosystems in the field at various scales, ranging from site-specific actions to the bioregional and landscape scale. Careful management of goods and environmental services, in forestry, agriculture, fishing, wildlife and tourism is a key factor in providing benefits to local residents and the national and global marketplace. Alternative approaches have been suggested to help maintain the values of biodiversity while addressing economic and social goals.

Closely allied with on-site measures are a whole range of off-site or *ex situ* mechanisms to maintain seed and tissue collections, propagate and breed endangered species, preserve reduced genetic strains, and offer methods of restoring communities and reintroducing species.

Governments, communities and industry (see, for example, Krattiger *et al.* 1994), poised to initiate and engage in biodiversity conservation and development efforts, may now draw upon methods and techniques based on the knowledge and experience from around the world. These experiences suggest that there now exists a full set of tools that will fit most situations. It is also clear that existing science, technology and information can help modify and adapt these tools to local conditions and values.

The limiting factor for developing and implementing successful biodiversity policies appears to be the capacity that each nation has available for managing its biotic wealth. More specifically, the success of biodiversity management programmes will depend greatly on how each nation encourages its human capacity to design and carry out intellectual and practical tasks ranging from inventorying to exploiting biotechnology. Various types of physical facilities and infrastructures are needed to house collections and training establishments, transport scientists and practitioners, foster research in sustainable technologies, and so on. Finally, there is the need for financial capacity. Various approaches have been shown to assist countries cover the financial costs of their biodiversity programmes, at least during initial phases, to establish such programmes.

Thus, existing knowledge, technology and information

suggest that countries can move forward with conservation and development plans, with the certainty that tools to help manage the associated activities are available. Countries are urged, however, to approach biodiversity management in an experimental mode, being prepared to adapt to changing conditions and information. Continuing research can be expected to provide policy-makers with a growing sense of certainty, even as new mysteries of nature are uncovered. Given the expectations of a growing population for food, fibre, water, air, medicines and a host of environmental services and spiritual values, there is little alternative to forging ahead, taking full advantage of existing knowledge, technology and information to help navigate in stormy seas with reasonable precision.

Acknowledgements

The co-ordinators of Section 13 wish, first of all, to thank each of the authors and contributors who have taken the time and effort to share their knowledge about the many dimensions of biodiversity management. They often did so without compensation and under very short deadlines. Participants at workshops in Nairobi and Bangalore to review Sections 11 and 13 also contributed in many ways to this Section. The co-ordinators are grateful to the nearly 100 reviewers around the world who contributed thoughtful and constructive suggestions to improve the content and accuracy of Section 13. Jane Scully is recognized for her editorial contributions to a lengthy and complex document. Not least, the research and administrative help of Donna Dwiggin, Lisa Sullivan, Joanna Napies, and Cathy Karr were indispensable to the production of Section 13.

Annex 1

Organization of the Global Biodiversity Assessment

The GBA is the result of a complex operation involving many organizations, institutions and individuals throughout the world. The overall structure is given in the accompanying box.

The organization of the GBA.

Ilkka Hanski, Finland	Rai Singh Rana, India	Jean-Denis Vigne, France

Section 4 Workshop II, Paris, 28–29 June 1995

Robert Barbault, France	Hiroya Kawanabe, Japan	Yannis Michalakis, France
Jean Clobert, France	Michel Loreau, France	Francois Renaud, France

Sections 5 and 6 Workshops

Tropical Savannahs
Brasilia, Brazil
24–28 May, 1993.

Organizers:

O.T. Solbrig, USA
E. Medina, Venezuela

Participants:

S. Archer, USA
Z. Baruch, Venezuela
J.A. Belsky, USA
B. Bilbao, Venezuela
R. Braithwaite, Australia
L. Bulla, Venezuela
M. Coughenour, USA
C. Dall’Agllo, Brazil
B. Dias, Brazil
G. W. Fernandez, Brazil
A.C. Franco, Brazil
I. Garay, Brazil
M. Haridasan, Brazil
J. Hay, Brazil
W. Hoffman, USA
C. Klink, Brazil
P. Lavelle, France
A. Moreira, Brazil
P. Oliveira, Brazil
J.F. Ribeiro, Brazil
G. Sarmiento, Venezuela
J. Silva, Venezuela
P. Stott, UK

Coastal Systems
Vancouver Island, Canada
21–25 September, 1992.

Organizers:

J. Lubchenco, USA
J.C. Castilla, Chile

Participants:

G. Branch, South Africa
R. Bustamante, Ecuador
V. Gerard, USA
E. Jaramillo, Chile
B. Menge, USA
P. Sanchez, Chile
B. Santelices, Chile
W. Stolz, Chile

Arid Zones
Canberra, Australia
31 January – 4 February, 1994.

Organizer:

I. Noble, Australia

Participants:

B. Fox, Australia
M. Fox, Australia
H. Gitay, Australia
L. Huenneke, USA
J. Landsberg, Australia
S. Lavorel, Australia
S. Morton, Australia
I. Noy-Meir, Israel
W.G. Whitford, USA

Estuaries, Lagoons, and Mangroves
Lafayette, Louisiana, USA
5–7 May, 1994.

Organizer:

R. Twilley, USA

Participants:

R. Chen, USA
E. Medina, Venezuela
V. Rivera-Monroy, USA
S.C. Snedaker, USA
A. Yanez-Arancibia, Mexico

Islands
Nassau, Bahamas
7–11 October, 1993.

Organizers:

P. Vitousek, USA
H. Adersen, Denmark
L. Loope, USA

Participants:

T. Bether, Bahamas
R.D. Bowden, USA
S. Buckner, Bahamas
E. Carey, Bahamas
J.H. Cushman, USA
C.M. D’Antonio, USA
T. Dudley, USA
U. Eliasson, Sweden
J.J. Ewel, USA
A.L. Flowers, Bahamas
D. Foote, USA
J.H. Fownes, USA
D. Given, New Zealand
R. Gnam, USA
P.J. Hearty, Bahamas
P. Hogberg, Sweden
D. Hooper, USA
M. Isaars, Bahamas
H.F. James, USA
K. Kaneshiro, USA
G. Larson, Bahamas
A.W. Macdonald, South Africa
P.A. Maillis, Bahamas
M. Maunder, UK
D. Mueller-Dombois, USA
N. Popou, Bahamas
J. Roughgarden, USA
J.T.S. Sahota, Switzerland
W. Strahm, Switzerland

S. Ward, Bahamas
D. Wedin, Canada
G.L. Woon, Bahamas

Tundra

Kongsvold, Norway
17–20 August, 1993.

Organizers:

F.S. Chapin, USA
C. Korner, Switzerland

Participants:

B. Ammen, Switzerland
L. Brubaker, USA
J. Bryant, USA
T. Callaghan, UK
G. Grabherr, Austria
A. Hershey, USA
S. Hobbie, USA
R. Jefferies, Canada
S. Jonasson, Denmark
G. Kling, USA
J.B. McGraw, USA
D. Murray, USA
J. O'Brien, USA
J. Pastor, USA
J. Schimel, USA
G. Shaver, USA
M. Walker, USA
O. Young, USA
S. Zimov, Russia

Tropical Forests

Oaxtepec, Mexico
4–7 December, 1993.

Organizers:

G. Orians, USA
R. Dirzo, Mexico

Participants:

P. Colinvaux, Panama
J.H. Cushman, USA
J. Denslow, USA
J.J. Ewel, USA
L. Gilbert, USA
S. Gliessman, USA
D.L. Hawksworth, UK
M. Huston, USA
V. Jaramillo, Mexico
D.J. Lodge, USA
A. Power, USA
M. Rejmanek, USA
W.L. Silver, USA
S.J. Wright, Panama

Coral Reefs

Key West, Florida, USA
1–7 November, 1993.

Organizers:

J. Ogden, USA
T. Done, Australia
B. Salvat, France

Participants:

D. Bellwood, Australia
J. Benzie, Australia

Lakes and Rivers

Madison, Wisconsin, USA
9–11 September, 1993.

Organizer:

S. Carpenter, USA

Participants:

T.M. Frost, USA
L. Persson, USA
M.E. Power, USA
D. Soto, Chile

Boreal Forests

Duluth, Minnesota, USA
18–21 January, 1993.

Organizer:

J. Pastor, USA

Participants:

David J. Mladenoff, USA
Yrjo Haila, Finland
John P. Bryant, USA
Serge Payette, Canada

Mediterranean Systems

Capetown, South Africa
9–11 September, 1992.

Organizer:

B. Huntley, South Africa

Participants:

A. Aronson, France
M.T.K. Arroyo, Chile
J. Blondel, France
W.J. Bond, South Africa
R.M. Cowling, South Africa
G.W. Davis, South Africa
E.R. Fuentes, Chile
R. Ginocchio, Chile
R.H. Groves, Australia
R.J. Hobbs, Australia
S.D. Hopper, Australia
F.M. Jaksic, Chile
J.E. Keeley, USA
R.J. Lambeck, Australia
B.B. Lamont, Australia
S. Lavorel, Australia
A.R. Main, Australia
J.D. Majer, Australia
G. Montenegro, Chile
H.A. Mooney, USA
D.M. Richardson, South Africa
P.W. Rundel, USA
M.C. Rutherford, South Africa
D.A. Saunders, Australia
W.D. Stock, South Africa
C. Swift, USA

Regional sub-meetings on

Mediterranean systems were held in Los Angeles, California, USA, 22 February, 1992.

Organizer:

J. Keeley, USA

Participants, USA:

M. Cody, F. Davis, J. Powell, M. Price,
J. Quinn, P. Rundel, C. Swift and
P. Zedler

Also in Perth, Australia, December 1991.

Organizer:

R. Hobbs, Australia

Participants, Australia:
R. Groves, R. Lambeck, B. Lamont, S. Lavorel, T. Lefroy, B. Main, J. Majer, D. Saunders and E. Witkowski

Temperate Grasslands
Stanford, California, USA
17–20 January, 1994.

Organizer:
O. Sala, Argentina

Participants:
W.K. Lauenroth, USA
S.J. McNaughton, USA
G. Rusch, Sweden
X. Zhang, China

Agroecosystems
Harpden, UK
17–21 January, 1994.

Organizer:
M. Swift, Kenya

Participants:
J. Vandermeer, USA
P.S. Ramakrishnan, India
C.K. Ong, Kenya
J.M. Anderson, UK
B. Hawkins, UK

Open Oceans
Boston, Massachusetts, USA
17–20 January, 1994.

Organizer:
L. Kaufman, USA

Participants:
C.A. Butman, USA
J.T. Carlton, USA
M. Chandler, Canada

S. Mulsow, Chile
E. Okemwa, Kenya
C. Stuart, USA

Keystone Species
Hilo, Hawaii, USA
8–11 December, 1994.

Organizers:
H. Mooney, USA
J. Lubchenco, USA

Participants:
W.J. Bond, South Africa
J.C. Castilla, Chile
G. Daily, USA
J.A. Estes, USA
B.A. Menge, USA
L.S. Mills, USA
R.T. Paine, USA
M. Power, USA
D. Tilman, USA

Synthesis Meeting
Asilomar, California, USA
27 February – 3 March, 1994.

Organizers:
H. Mooney, USA
J.H. Cushman, USA

Participants:
J.M. Anderson, UK
A. Austin, USA
E.H. Bucher, Argentina,
I.C. Burke, USA
C.A. Butman, USA
J.T. Carlton, USA
S. Carpenter, USA

Annex 6

Glossary

accession	a sample of a crop variety collected at a specific location and time; may be of any size.
actual evaporation	estimate of how much of the existing precipitation could be evaporated or transpired from a standard ‘sward’ of grass on a standard soil.
adaptation	a genetically determined characteristic that enhances the ability of an organism to cope with its environment.
adaptive landscape	a graph of the average fitness of a population in relation to the frequencies of genotypes in it: peaks on the landscape correspond to genotypic frequencies at which the average fitness is low.
adaptive radiation	evolutionary diversification of species derived from a common ancestor into a variety of ecological roles.
adaptive zone	a particular type of environment requiring unique adaptations then allowing adaptive radiation to occur.
agroecology	the use of ecological concepts and principles to study, design, and manage agricultural systems. Agroecology seeks to evaluate the full effect of system inputs and outputs by integrating cultural and environmental factors into the analysis of food production systems and to use this knowledge to improve these systems, taking into account the needs of both the ecosystem as a whole and the people within it.
agroforestry	a collective name for land-use systems and technologies where woody perennials (trees, shrubs, palms, bamboos, etc.) are deliberately used on the same land management unit as agricultural crops and /or animals, either in some form of spatial arrangement or temporal sequence.
alien species	<i>see</i> introduced species.
Allee effect	phenomenon in which survival of individuals is increased by aggregation.
allele	one of several alternatives of a gene.

allopatric	occupying different geographical ranges.
allopatric speciation	speciation via geographically separated populations.
apoendemic	polyploid endemics that are derived from widespread species of a lower ploidy level.
aquaculture	breeding and rearing fish, shellfish, etc., or growing plants for food in special ponds.
artificial insemination	a breeding technique, most commonly used in domestic animals and sometimes in captive breeding of wild animals, in which semen is introduced into the female reproductive tract by artificial means.
artificial selection	selective breeding, carried out by humans, to produce a desired evolutionary response.
assets	goods that provide a flow of services over time.
baseline data	fundamental units of basic inventory information that are crucial for biodiversity conservation planning and management. These are both biotic and abiotic and usually include: (1) the presence and/or abundance of species and other units; (2) other dependent biotic data (e.g. plant cover for macroarthropods); (3) the appropriate influential abiotic variables, and (4) human variables.
benthos	living at the bottom of the sea or a lake.
bequest value	value, defined by willingness to pay, to ensure that peoples' offspring or future generations inherit a particular environmental asset.
biocoenosis	varied community of organisms living in the same small area, e.g. in the bark of a tree.
biogeography	the scientific study of the geographic distribution of organisms.
biological control	control of pests by using predators to eat them.
biological resources	those components of biodiversity of direct, indirect, or potential use to humanity.
biome	a major portion of the living environment of a particular region (such as a coniferous forest or grassland), characterized by its distinctive vegetation and maintained by local climatic conditions.
biopesticide	pesticide made from biological sources, that is from toxins which occur naturally.
bioregion	a territory defined by a combination of biological, social, and geographic criteria, rather than geopolitical considerations; generally, a system of related, interconnected ecosystems.
biosphere reserve	established under UNESCO's Man and the Biosphere (MAB) Programme, biosphere reserves are a series of protected areas linked through a global network, intended to demonstrate the relationship between conservation and development.
biotope	small area with uniform biological conditions (climate, soil, altitude, etc.).

biotype	group of genetically identical individuals.
buffer zone	the region near the border of a protected area; a transition zone between areas managed for different objectives.
breed	a group of animals or plants related by descent from common ancestors and visibly similar in most characteristics. Taxonomically, a species can have numerous breeds.
Cambrian	the earliest period of the Palaeozoic era, extending from 500 to 550 million years ago.
captive breeding	the propagation or preservation of animals outside their natural habitat (see <i>ex situ</i> conservation), involving control by humans of the animals chosen to constitute a population and of mating choices within that population.
centre of diversity	an area with a high number of species, which might be recognized on a global, regional or local scale.
character	any recognizable trait, feature, or property of an organism.
chemicalization	accumulation of unnatural concentrations of certain chemical compounds.
clade	set of species from a common ancestral species.
clear-cutting	the removal of the entire standing crop of trees. In practice, may refer to exploitation that leaves much unsaleable material standing (e.g. a commercial clear-cutting).
clone	a set of genetically identical organisms asexually reproduced from one ancestral organism.
co-adaptation	evolution of characteristics of two or more species to their mutual advantage.
co-evolution	evolution in two or more interacting species in which the evolutionary changes of each species influence the evolution of the other species.
co-management	the sharing of authority, responsibility, and benefits between government and local communities in the management of natural resources.
common property resource management	the management of a specific resource (such as a forest or pasture) by a well-defined group of resource users with the authority to regulate its use by members and outsiders.
community	all the organisms that live in a given habitat and affect one another as part of the food web or through their various influences on the physical environment.
compensating variation	the change in income necessary to restore the consumer to its original level of utility after a price change.
competition	use or defence of a resource by one individual that reduces the availability of the resource to other individuals.

competitive exclusion	the extinction of one species by another species in the same area through competition.
conservation	judicious use and management of nature and natural resources for the benefit of human society and for ethical reasons.
conservation values	the value to society of conserving environmental resources.
cost–benefit analysis (CBA)	the appraisal of an investment project which includes all social and financial costs and benefits accruing to the project.
counterurbanization	selling your apartment and buying a tent.
crossing over	the process in which the chromosomes of a diploid pair exchange genetic material. It produces genetic recombination.
cryogenic storage	the preservation of seeds, semen, embryos, or microorganisms at extremely low temperatures, below -130°C . At these temperatures, water is absent, molecular kinetic energy is low, diffusion is virtually nil, and storage potential is expected to be extremely long.
cultivar	a cultivated variety (genetic strain) of a domesticated crop plant.
debt-for-nature swaps	a conservation agency buys up some of a developing country's international debt ('secondary' debt) on the world's money market. The agency then promises to dispose of the debt in return for a promise from the indebted country that it will look after a conservation area.
demography	the study of birth rates, death rates, age distributions, and size of populations. It is a fundamental discipline within the larger field of population biology and ecology.
development values	the value to society of converting environmental resources to development uses.
derived demand approach	<i>see</i> Revealed Preference Approach.
diploid	having two sets of genes and two sets of chromosomes – one from the female parent, one from the male parent.
direct use value	economic values derived from direct use or interaction with a biological resource or resource system.
direct valuation approach	<i>see</i> Stated Preference Methods.
directional selection	selection leading to a consistent directional change in any character of a population through time, for example selection for larger eggs.
discounting	lowering the importance that is attached to gains and losses in the future.
dispersal	movement of organisms away from place of birth.
disruptive selection	selection favouring individuals that deviate in either direction from the population average. Selection favours individuals that are larger or smaller than average.
domestication	the process by which plants, animals or microbes selected from the wild adapt to a special habitat created for them by humans.

domesticates	organisms that have undergone domestication.
domestic biodiversity	the genetic variation existing among the species, breeds, cultivars and individuals of animal, plant and microbial species that have been domesticated, often including their immediate wild relatives.
DNA	deoxyribonucleic acid, the molecule that controls inheritance.
drift	<i>see</i> genetic drift.
ecosystem	a dynamic complex of plant, animal, fungal, and micro-organism communities and their associated non-living environment interacting as an ecological unit; the organisms living in a given environment, such as a tropical forest or a lake, and the physical part of the environment that impinges on them.
ecosystem rehabilitation	the recovery of specific ecosystem services in a degraded ecosystem or habitat.
ecosystem/ecological resilience	ecological resilience can be defined in two ways. The first is as a measure of the magnitude of disturbance that can be absorbed before the (eco)system changes its structure by changing the variables and processes that control behaviour. The second, a more traditional meaning, is as a measure of resistance to disturbance and the speed of return to the equilibrium state of an ecosystem.
ecosystem restoration	the return of an ecosystem or habitat to its original community structure, natural complement of species, and natural functions.
ecosystem services/ ecological services	ecological processes or functions which have value to individuals or society.
ecotourism	travel undertaken to witness sites or regions of unique natural or ecological quality, or the provision of services to facilitate such travel.
edge effect	processes that characterize habitat fragmentation and the concomitant creation of edges.
endemic	restricted to a specified region or locality.
equilibrium theory	theory that suggests that under natural circumstances, species addition and loss are balanced, and furthermore, that displacement from the equilibrium value results in changes in speciation or extinction rate that tend to restore the system to its equilibrium state.
equity	the opposite of inequity.
equivalent variation	an income change that is equivalent which has the same effect on utility or welfare as a price.
ethical values	statements of ethical principle that inform the private and social valuation of biological resources.
ethnobiology	study of the way plants, animals and micro-organisms are used by humans.
eukaryote	an organism whose DNA is enclosed in nuclear membranes. The vast majority of species are eukaryotic.

eutrophication	process by which a lake becomes full of phosphates and other nutrients which encourage the growth of algae and kill other organisms.
existence value	the value of knowing that a particular species, habitat or ecosystem does and will continue to exist. It is independent of any use that the valuer may make of the resource.
ex situ conservation	keeping components of biodiversity alive away from their original habitat or natural environment.
external costs/externalities	external costs/benefits exist when an activity by one person causes a gain/loss of welfare to another person that is uncompensated within the market
extinction	the death of any lineages of organisms. Extinction can be local, (when it is known as extirpation) in which one population of a given species vanishes while others survive elsewhere, or total, in which all its populations vanish.
extractive reserve	forest area for which use rights are granted by governments to residents whose livelihoods customarily depend on extracting forest products from the specified area.
fallow	the period during which land is left to recover its productivity (reduced by cropping) mainly through accumulation of water, nutrients, attrition of pathogens, or a combination of all three. During this period, the land may be bare or covered by natural or planted vegetation. The term may be applied to the land itself or to the crop growing on it.
fauna	all of the animals found in a given area.
fecundity	rate at which females produce offspring.
fitness	the expected contribution of an allele, genotype, or phenotype to future generations. the fitness of genes and organisms is always relative to the other genes and organisms that are present in the same population. Usually it is measured as the average number of offspring produced by individuals with a certain genotype, relative to the number produced by other genotypes.
flagship species	popular, charismatic species that serve as symbols and rallying points to stimulate conservation awareness and action.
flora	all of the plants found in a given area.
Flora	a book listing, with descriptions, all plants that grow in a particular area.
food web	an abstract representation of the various paths of energy flow through populations in the community.
founder effect	the loss of genetic diversity when a new colony is formed by a very small number of individuals from a larger population.
fragmentation	the breaking up of extensive landscape features into disjunct, isolated, or semi-isolated patches as a result of land-use changes.
free-rider problem of public goods	because the use of public goods by one person does not exclude others, each user has an incentive to allow others to pay the cost of the public good.

functional diversity	this can refer to two rather different concepts: the diversity of the ecological functions performed by different species, and the diversity of species performing a given ecological function.
gene	the functional unit of heredity. It is part of the DNA molecule that encodes a particular protein.
gene bank	a storage facility where germplasm is stored in the form of seeds, pollen, embryos, semen, pollen, or <i>in vitro</i> culture, or in cryogenic storage, or, in the case of a field gene bank, as plants growing in the field.
gene flow	exchange of genetic traits between populations by movement of individuals, gametes or spores.
genetic diversity	variation in the genetic composition of individuals within or among species; the heritable genetic variation within and among populations.
genetic drift	random gene frequency changes in a small population due to chance alone.
genetic erosion	loss of genetic diversity between and within populations of the same species over time; or reduction of the genetic basis of a species due to human intervention, environmental changes, etc.
genetic resources	genetic material of plants, animals or micro-organisms, including modern cultivars and breeds, primitive varieties and breeds, landraces and wild/weedy relatives of crop plants or domesticated animals, of value as a resource for future generations of humanity.
genome	all the genes of a particular organism or species.
genotype	the entire genetic constitution of an organism, or the genetic composition at a specific gene locus or set of loci.
germplasm	a set of different genotypes that may be conserved and used; the genetic material, especially its specific molecular and chemical constitution, that comprises the physical basis of the inherited qualities of an organism.
guild	a group of species found in the same place that share the same food resource. Example: the lizard species of a sand dune that feed on insects.
habitat	the space used by an organism, together with the other organisms with which it coexists, and the landscape and climate elements that affect it; the place where an animal or a plant normally lives and reproduces.
haploid	cell or organism that contains one set of chromosomes.
heterosis	situation in which the heterozygote has a higher fitness than either homozygote.
heterozygosity	genetic variability among individuals within populations and variability among populations.
homozygote	individual having two copies of the same allele at a genetic locus.
hybridization	crossing of individuals from genetically different strains, populations or species.

hybrid zone	region of reproduction among individuals of different species.
inbreeding	mating among related individuals.
inbreeding depression	a reduction in fitness and vigour of individuals as a result of increased homozygosity through inbreeding in a normally outbreeding population.
<i>in situ</i> conservation	the conservation of biodiversity within the evolutionary dynamic ecosystems of the original habitat or natural environment.
<i>in situ</i> gene banks	protected areas designated specifically to protect genetic variability of particular species.
income	a flow of money, goods or services deriving from the productive use of assets.
indicator species	a species whose status provides information on the overall condition of the ecosystem and of other species in that ecosystem. Species which flag changes in biotic or abiotic conditions. They reflect the quality and changes in environmental conditions as well as aspects of community composition.
indigenous peoples	people whose ancestors inhabited a place or country when persons from another culture or ethnic background arrived on the scene and dominated them through conquest, settlement, or other means and who today live more in conformity with their own social, economic, and cultural customs and traditions than with those of the country of which they now form a part. (Also: ‘native peoples’ or ‘tribal peoples’.)
indirect use or derived value	economic value derived from the role of resources and systems in supporting or protecting activities whose outputs have direct value in production or consumption.
indirect valuation methods	<i>see</i> Revealed Preference Approach.
inefficiency	an allocation of resources is said to be inefficient if there is another allocation such that one person can be made better off without making anyone worse off.
infochemical	information in the form of chemical substances.
instrumental values	<i>see</i> Use Values.
insurance value	the value of biodiversity in maintaining ecosystem functions over a range of environmental conditions.
integrated pest management	an ecologically based strategy that relies on natural mortality factors, such as natural enemies, weather, and crop management, and seeks to control tactics that disrupt these factors as little as possible while enhancing their effectiveness.
intellectual property right	a right enabling an inventor to exclude imitators from the market for a limited time.
intergenerational equity	a core proposition is that future generations have a right to an inheritance (capital bequest) sufficient to allow them to generate a level of well-being no less than that of the current generation. Fairness in the treatment of different members of the same generation.

introduced species	a species occurring in an area outside its historically known natural range as a result of intentional or accidental dispersal by human activities. (Also known as an exotic or alien species.)
introgression	incorporation of genes of one species into a gene pool of another species.
invasive species	an introduced species which invades natural habitats.
inventorying	the surveying, sorting, cataloguing, quantifying and mapping of entities such as genes, individuals, populations, species, habitats, ecosystems and landscapes or their components, and the synthesis of the resulting information for the analysis of process.
iron law of the discount rate	species with a growth rate less than the rate of discount will be optimally driven to extinction unless extraction is regulated or the growth in the value of the species compensates for the difference.
joint products	commodities which are produced in such a way that a change in the output of one of them necessarily involves a change in the output of the other.
karyotype	characteristic chromosomes of a species.
keystone species	a species whose loss from an ecosystem would cause a greater than average change in other species populations or ecosystems processes; species that have a disproportionately large effect on other species in a community.
landrace	a crop cultivar or animal breed that evolved with and has been genetically improved by traditional agriculturalists, but has not been influenced by modern breeding practices.
land tenure	the right to exclusively occupy and use a specified area of land. Tenure may also be limited to certain resources ('resource tenure') such as timber but not to all resources in a given area. Tenure may be held by individuals, communities, government, or corporations.
large marine ecosystems	regions of ocean space encompassing coastal areas from river basins to estuaries to the seaward boundary of continental shelves and seaward margins of coastal current systems. They are relatively large regions, characterized by distinct bathymetry, hydrography, productivity and trophically linked populations.
locus	the site on a chromosome occupied by a specific gene.
macroevolution	large-scale evolution, entailing major changes in biological traits.
managed forest	productive forest where harvesting regulations are enforced, silvicultural treatments are carried out, and trees are protected from fires and diseases.
marginal values	the change in the value of a resource that is due to an incremental change in its quantity.
market failure	this occurs when market prices are not equal to the social opportunity cost of resources. External effects or externalities are evidence of market failure.

market prices	prices generated through a market mechanism. When all costs and benefits (societal) have not been taken into account, this may be less than the social cost.
maximum sustainable yield	the largest yield that can be obtained which does not deplete or damage natural resources irreparably and which leaves the environment in good order for future generations.
Mesozoic	era extending from 245 to 66 million years ago.
metapopulation	a set of partially isolated populations belonging to the same species. The different populations are able to exchange individuals and recolonize sites in which the species has recently become extinct.
microevolution	evolutionary changes on the small scale, such as changes in gene frequencies within a population.
minimum viable population	the smallest isolated population having a good chance of surviving for a given number of years despite the foreseeable effects of demographic, environmental, and genetic events and natural catastrophes. (The probability of persistence and the time of persistence are often taken to be 99% and 1000 years, respectively.)
monitoring	the intermittent (regular or irregular) surveillance to ascertain the extent of compliance with a predetermined standard or degree of deviation from an expected norm (Hellawell 1991).
monophyletic group	set of species containing a common ancestor and all its descendants.
mutation	any change in the genotype of an organism occurring at the gene, chromosome or genome level.
mutualism	interspecific relationship in which both organisms benefit. Example: flower pollination by insects.
native species	plants, animals, fungi, and micro-organisms that occur naturally in a given area or region.
natural forest management system	controlled and regulated harvesting of forest trees, combined with silvicultural and protective measures, to sustain and increase the commercial value of subsequent stands; relies on natural regeneration of native species.
natural selection	process by which the genotypes in a population that are best adapted to the environment increase in frequency relative to less well-adapted genotypes over a number of generations.
neoendemics	clusters of closely related species and subspecies that have evolved relatively recently.
net present value	the discounted value of the net benefits of use of a resource.
niche	the place occupied by a species in its ecosystem and its role: where it lives, what it feeds on and when it performs all its activities.
nitrogen fixation	biological assimilation of atmospheric nitrogen to form organic nitrogen-containing compounds.

non-consumptive value non-use or passive use value	the value of resources which are not diminished by their use. Values that do not require access to or active use of a biological resource by the valuer. Passive use value may imply that the resource is used by other humans whose welfare matters to the valuer. It therefore includes vicarious use value, bequest value and existence value.
non-equilibrium theory	suggests that the number of species increases or decreases depending on how the environment influences species production, exchange and extinction at any particular time.
non-exclusive goods	public goods to which it is impossible, or excessively costly, to operate any exclusion mechanism.
non-rival goods (in consumption)	public goods whose consumption by one individual does not preclude consumption by others.
normalizing selection	selection favouring individuals in the middle of the distribution of phenotypes in a population and disfavours the extremes (also called: stabilizing selection).
nucleotide	unit building block of DNA. It consists of a sugar and phosphate backbone with a base attached.
null model	the model of no effect.
opportunity cost	the value of the best alternative use of a resource. This consists of the maximum value of other outputs we could and would have produced had we not used the resource to produce the item in question.
option value	the potential value of the resource for future (direct or indirect) use.
parapatric speciation	speciation in which the new species forms from a population contiguous with the ancestral species' geographic range.
parasite	an organism that consumes part of the tissues of its host, usually without killing the host.
parasitoid	kind of insect whose larvae develop within and kill their host.
parataxonomists	explicitly trained lay professionals who collect specimens and other information for Costa Rica's national Biodiversity Institute (INBio) from their biodiversity offices in or near the Conservation Areas.
patroendemics	restricted diploid species that have spawned younger, widespread polyploid species.
palaeoendemics	phylogenetically high-ranking taxa that might be regarded as evolutionary relicts; also ancient isolated taxa with high ploidy levels, whose diploid ancestors are extinct or unknown.
perfect complements	resources which are always used in fixed proportions to each other. Left shoes and right shoes are said to be perfect complements.
perfect substitutes	resources which are always used as replacements for each other.

Permian	last period of the Palaeozoic era, extending from 290 to 245 million years ago.
Phanerozoic	the major division of geological time during which most biodiversity has evolved and existed, 550 million years ago to the present.
phenotype	the observed traits of an organism, resulting from an interaction of its genotype and its environment.
phyletic evolution	genetic changes that occur within an evolutionary line.
phylogenetic	pertaining to the evolutionary history of a particular group of organisms.
phylum	the highest level of classification below the kingdom. For instance, Mollusca (slugs, snails, clams, etc.) constitute a phylum.
plant functional attributes	readily observable features of vegetation that are considered significant for growth, physiology and survival (for example pollination mechanisms, seed dispersal mechanisms, rooting systems).
plasmid	a genetic element that exists independently of the main DNA in the cell. In bacteria, plasmids appear as small loops of DNA, able to pass between cells independently.
Pleistocene	the span of geological time preceeding the Recent epochs, during which the human species evolved. It began 2.5 million years ago and ceased with the end of the last Ice Age 10 000 years ago.
ploidy	number of chromosome sets contained by a cell: 1 = haploid, 2 = diploid and so on.
policy failure	occurs when government policies do not correct for market failures.
polyploid	organism containing two or more sets of genes or chromosomes.
population	a group of individuals with common ancestry that are much more likely to mate with one another than with individuals from another such group.
population viability analysis (PVA)	a comprehensive analysis of the many environmental and demographic factors that affect survival of a population, usually small.
potential evapotranspiration	measure of total heat flux.
precautionary principle (PP)	if the costs of current activities are uncertain, but are potentially both high and irreversible, the precautionary principle holds that society should take action before the uncertainty is resolved.
predator	an animal that kills and eats animals.
preferences	these are the orderings of different bundles of goods according to the wants of the consumer in question. Preferences may be influenced by ethical values, culture, age, gender and other political, social and demographic variables.
primary forest	relatively intact forest that has been essentially unmodified by human activity.
primary value	the value of the system characteristics upon which all ecosystem functions depend.

private opportunity cost	the opportunity cost faced by an individual agent of using a resource (not including any externalities).
private value	the value to the private agent of using or refraining from using a resource.
production function	this describes the outputs that may be obtained from combining different quantities of inputs.
prokaryote	cell without a distinct nucleus. Bacteria are prokaryotic.
proportional sampling	the alternative to saturation; when the local richness increases proportionately with the size of the regional species pool when the sample area is held constant.
protected area	a legally established land or water area under either public or private ownership that is regulated and managed to achieve specific conservation objectives.
public good	a good which, once provided to one user, must be provided in the same amount to all users due to its non-rival and non-excludable nature.
quasi-option value	the value of the future information made available through the preservation of a resource.
Quaternary period	the second and last period of the Cenozoic era extending from 2.5 million years ago to the present.
rational expectations	the hypothesis that decision-makers base their decisions on predictions which contain no systematic errors.
recalcitrant seed	seed that does not survive drying and freezing.
reciprocal externality	these are externalities where all parties using some resource impose external costs on all others.
resource	a substance or place required by an organism for its growth, maintenance and reproduction.
revealed preference approach	these approaches, which include derived demand approaches and indirect valuation methods, infer values from data on behavioural changes in actual markets related in some way to the missing market(s).
rights	entitlements assured by custom, law or property.
risk	the outcome of an action is said to involve risk where: the set of all possible outcomes of that action is known, and where the probability distribution of all possible outcomes is also known.
safe minimum standard	a restriction (taboo, prohibition, harvesting season) which limits the use of resources to levels that are thought to be safe, e.g. conservation of a sufficient area of habitat to ensure the continued provision of ecological functions and services, at the ecosystem level.
schizoendemics	vicariant species of equal ploidy level, resulting from either gradual or rapid divergence.

scramble competition	exploitation of a resource by one individual that reduces the availability of that resource to others. Usually also called ‘indirect competition’, because there is no direct interaction between competing individuals (see direct competition).
secondary forest	natural forest growth after some major disturbance (eg. logging, serious fire, or insect attack).
secondary value	the value of ecosystem functions.
seed bank	a facility designed for the <i>ex situ</i> conservation of individual plant samples through seed preservation and storage.
sibling species	species so similar to each other as to be difficult to distinguish by human observers.
silviculture	the science of cultivating forest crops (usually timber), based on a knowledge of forest tree characteristics.
social value	<i>see</i> Social Opportunity Cost.
social opportunity cost	the opportunities forgone by society, including externalities, in using a resource in some way. For biological resources this may be different than the market price of that resource.
speciation	separation of one population into two or more reproductively isolated, independent evolutionary units.
species diversity	the number and variety of species found in a given area in a region.
species richness	the number of species within a region. (A term commonly used as a measure of species diversity, but technically only one aspect of diversity.)
species selection	the differential multiplication and extinction of species as a result of differences in certain traits possessed by the organisms belonging to the various species, and causing a spread of the favouring traits through the fauna or flora as a whole.
stabilizing selection	selection favouring individuals in the middle of the distribution of phenotypes in a population and disfavours the extremes. Also called normalizing selection.
stated preference methods	a survey instrument is designed in which a market-like situation is constructed. These include direct valuation approaches, like contingent valuation method.
stochastic	referring to patterns or processes resulting from random factors.
strong sustainable development principle	the opportunity set for future generations can only be assured if the level of biodiversity they inherit is no less than that available to present generations.
subsidies	government grants to suppliers of goods or services.
subspecies	groupings or populations within a species that are distinguishable by morphological characteristics or, sometimes, by physiological or behavioural traits.
surrogate markets	markets used in place of the missing markets for environmental resources. Surrogate markets are at least existing markets for resources with some of the properties of the non-marketed resource being valued.

sustainable development	development that meets the needs and aspirations of the current generation without compromising the ability to meet those of future generations.
sympatric	occurring in the same place.
sympatric speciation	speciation via populations with overlapping geographic ranges.
taxon (pl. taxa)	the named classification unit (e.g. <i>Mus musculus</i> , Muridae, or Mammalia) to which individuals, or set of species, are assigned. Higher taxa are those above the species level.
Tertiary period	the first period of the Cenozoic era, beginning 66 million years ago and closing with the start of the Pleistocene, 2.5 million years ago.
tetraploid	referring to a cell or organism containing four sets of chromosomes (<i>see</i> ploidy).
theory of local existence	suggests that the number of species increases or decreases depending on how the environment influences species production, exchange and extinction at any particular time.
threatened species	species that are, often genetically impoverished, of low fecundity, dependent on patchy or unpredictable resources, extremely variable in population density, persecuted or otherwise prone to extinction in human-dominated landscapes.
tissue culture	a technique in which portions of a plant or animal are grown on an artificial culture medium (also ' <i>in vitro</i> culture').
total economic value	the sum of use and non-use values with due consideration of any trade-offs or mutually exclusive uses or functions of the resource/habitat in question.
total environmental value	it is a function of primary value and total economic value.
tracheophyte	a plant with tracheae or vessels such as flowering plants and ferns.
translocation	switching of a segment of a chromosome to another chromosome.
triploid	referring to a cell or organism containing three sets of chromosomes (<i>see</i> ploidy).
trophic	pertaining to food or nutrition.
umbrella species	species whose occupancy area (plants) or home range (animals) are large enough and whose habitat requirements are wide enough that, if they are given a sufficiently large area for their protection, will bring other species under that protection.
uncertainty	the outcome of an action is said to involve uncertainty where the set of all possible outcomes of that action is unknown, and where the probability distribution of all possible outcomes is also unknown.
unidirectional externality	these are externalities in which the external costs or benefits of the resource use are 'one way.'
use value	values obtained through the use of a resource. This includes direct and indirect use values and instrumental values. Preservation in this sense is as much a use as development

utility function	a description of the way in which the well-being of individuals depends on different combinations of goods and services consumed.
valuation	this is a method for determining the importance of environmental consequences of economic activity that are not taken into account in market transactions.
variance	a statistical measure of the dispersion of a set of values about its mean.
variety	<i>see</i> cultivar.
vicariant patterns	when several taxa are subdivided by the same tectonically and climatically produced barriers to dispersal.
vicarious use value	altruistic value of benefits received by friends, relatives or others who are users of a resource. This is a passive use value.
voucher specimens	collections of organisms that are maintained to provide permanent, physical documentation of species identifications and associated data resulting from inventories.
weak complementarity	this describes a relation between a marketed/produced good and a non-marketed environmental good. If consumption expenditure is zero on the marketed/produced good, then the marginal utility of the public good is also zero.
welfare	an index of well-being.
wild relative	plant or animal species that are taxonomically related to crop or livestock species and serve as potential sources for genes in breeding of new varieties of those crops or livestock.
willingness to pay (WTP)	WTP is the amount an individual is willing to pay to acquire some good or service. This may be elicited from stated or revealed preference approaches.
willingness to accept (WTA)	WTA is the amount of compensation an individual is willing to take in exchange for giving up some good or service. This may be elicited from stated or revealed preference approaches.

 genetic resources, 869–872
 value of parks and protected areas, 876–878
 value of species, 872–876
 summary, 878
 stated preference methods, 845–848
 contingent ranking, 846–848
 northern spotted owl case study, 873–874
 contingent valuation, 845–846, 884
 survey, 877
 structural adjustment programmes and policies, 894–895
 Total Environmental Value and Total Economic Value, 830, 843
 use value, 839–844
 habitats vs ecosystems, 841–843
 non-use value, non-use value example, 844–845
 species vs habitats, 839–841
 typology of values, 835–836
 summary, 843–844
 wild resources, estimates of direct use value, list, 866
 willingness to pay (WTP) and willingness to accept (WTA), 858–859, 872–874
 summaries, 827–828, 857–858, 904
 Vanuatu, private reserves and land-leasing, 1033–1034
 vectors, 161
 vegetation cover
 future prospects, 797
 and land use monitoring, 523–527
 videography, remote sensing, 498–499
 Virgin Islands National Park, 1031
